The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

WELLCOVORIN® TABLETS

(leucovorin calcium)

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.[1]

[1] Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

LIBRARY OF MEDICINE

WELLCOVORIN® TABLETS
(leucovorin calcium)
Leucovorin in convenient 5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m^2 orally or parenterally followed by 10 mg/m^2 orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m^2 every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

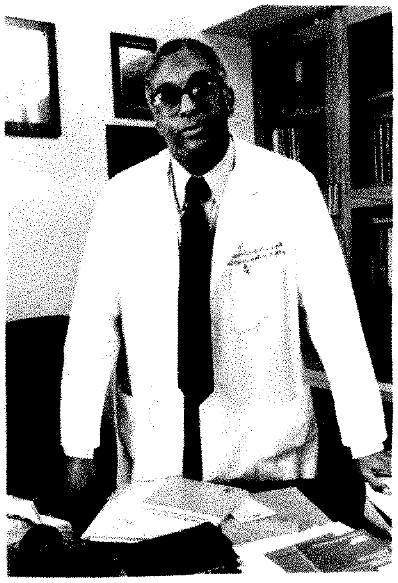
THIS SPACE CONTRIBUTED AS A PUBLIC SERVICE

You can help us raise the colorectal cancer cure rate.



"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkup Guidelines for men and women over 50 without symptoms:
- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces cancer alone.

AMERICAN CANCER SOCIETY®

BLOOD

The Journal of
The American Society of Hematology

Blood: The Journal of The American Society of Hematology (ISSN 0006-4971) is published monthly, in two volumes per year, by Grune & Stratton, Inc., 210 West Washington Square, Philadelphia, PA 19106. Second class postage paid at Duluth, MN, and at additional mailing offices.

POSTMASTER: Send change of address to *Blood*, c/o Grune & Stratton, Inc., PO Box 6280, Duluth, MN 55806.

Editorial correspondence should be addressed to:

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

Correspondence regarding subscriptions or change of address should be addressed to Grune & Stratton, Inc., PO Box 6280, Duluth, MN 55806.

Customer Service: 1-800-654-2452.

Change of address notices, including both the old and new addresses of the subscriber, should be sent to the Publisher at least one month in advance.

Other correspondence (copyediting, production) should be addressed to:

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

Monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

Monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors

SPECIAL DEPARTMENTS

Announcements 1704

Information for Contributors .... xlix, l

Effective January 1, 1987, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

All manuscripts submitted for consideration for publication in BLOOD should be sent to: John W. Adamson, MD, Editor, BLOOD, University District Building—Room 410, 1107 NE 45th St, Seattle, WA 98105. Telephone: (206) 545-8080. Please note that a processing fee of $50.00 must accompany each manuscript submitted for publication in BLOOD.

The American Society of Hematology certifies that the continuing medical education offering provided by *BLOOD, The Journal of The American Society of Hematology,* meets the criteria for up to 22 hours of credit in Category 5(a) for the Physician's Recognition Award of the American Medical Association.

As of December 1, 1987 all manuscripts submitted for consideration for publication in BLOOD should be sent to: Arthur W. Nienhuis, M.D., Editor, BLOOD, The Journal of the American Society of Hematology, 9650 Rockville Pike, Bethesda, MD 20814.

SIGMA DIAGNOSTIC

NOT NE JUST BET

Back when there was little to choose from in the way of highly specialized eukemia cell markers, such studies were long and tedious. Not to mention expensive. Although TdT investigation is still not as convenient as some other cytochemical studies—Sigma Diagnostics new TdT kit effectively reduces benchwork, while yielding slides with superior staining characteristics.

EASY straightforward reactions with a minimum of steps for optimal enzyme identification.

BRIGHT AND CLEAR visualization of TdT-positive cells achieved by a unique reaction sequence.

HIGH AVIDITY MONOCLONAL REAGENT assures location of all nuclear TdT, while eliminating indiscriminate cellular interactions.

HIGHLY SENSITIVE streptavidin-biotin immunoperoxidase reaction enhances total TdT detection.

FASTEST PROCEDURE coupling rapid fixation with shortened incubations and rinsing.

LESS COSTLY because of time-saving techniques and more reagent for 50% more slides.

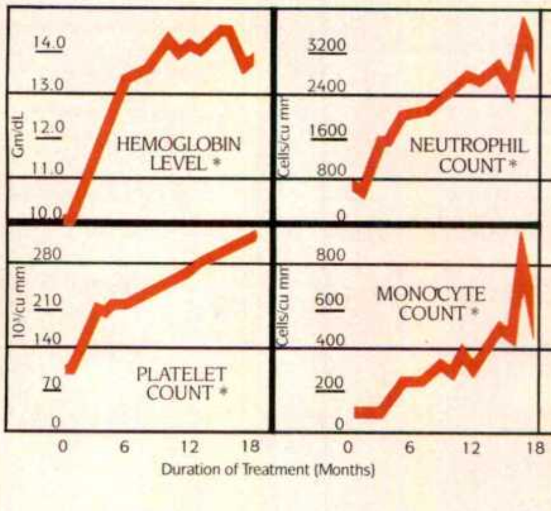
For research only; not for use in diagnostic procedures.

MAKING THINGS BETTER IS A SIGMA TRADITION.

In hairy cell leukemia

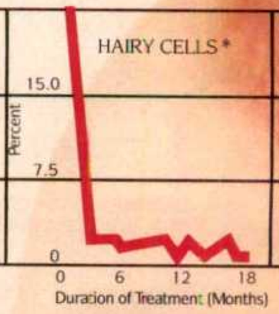
Restore normal patterns

Normalize blood parameters



- Virtually all patients benefit: 89% improved, 11% stabilized.
- Effective in all stages of disease.

Reduce tumor burden



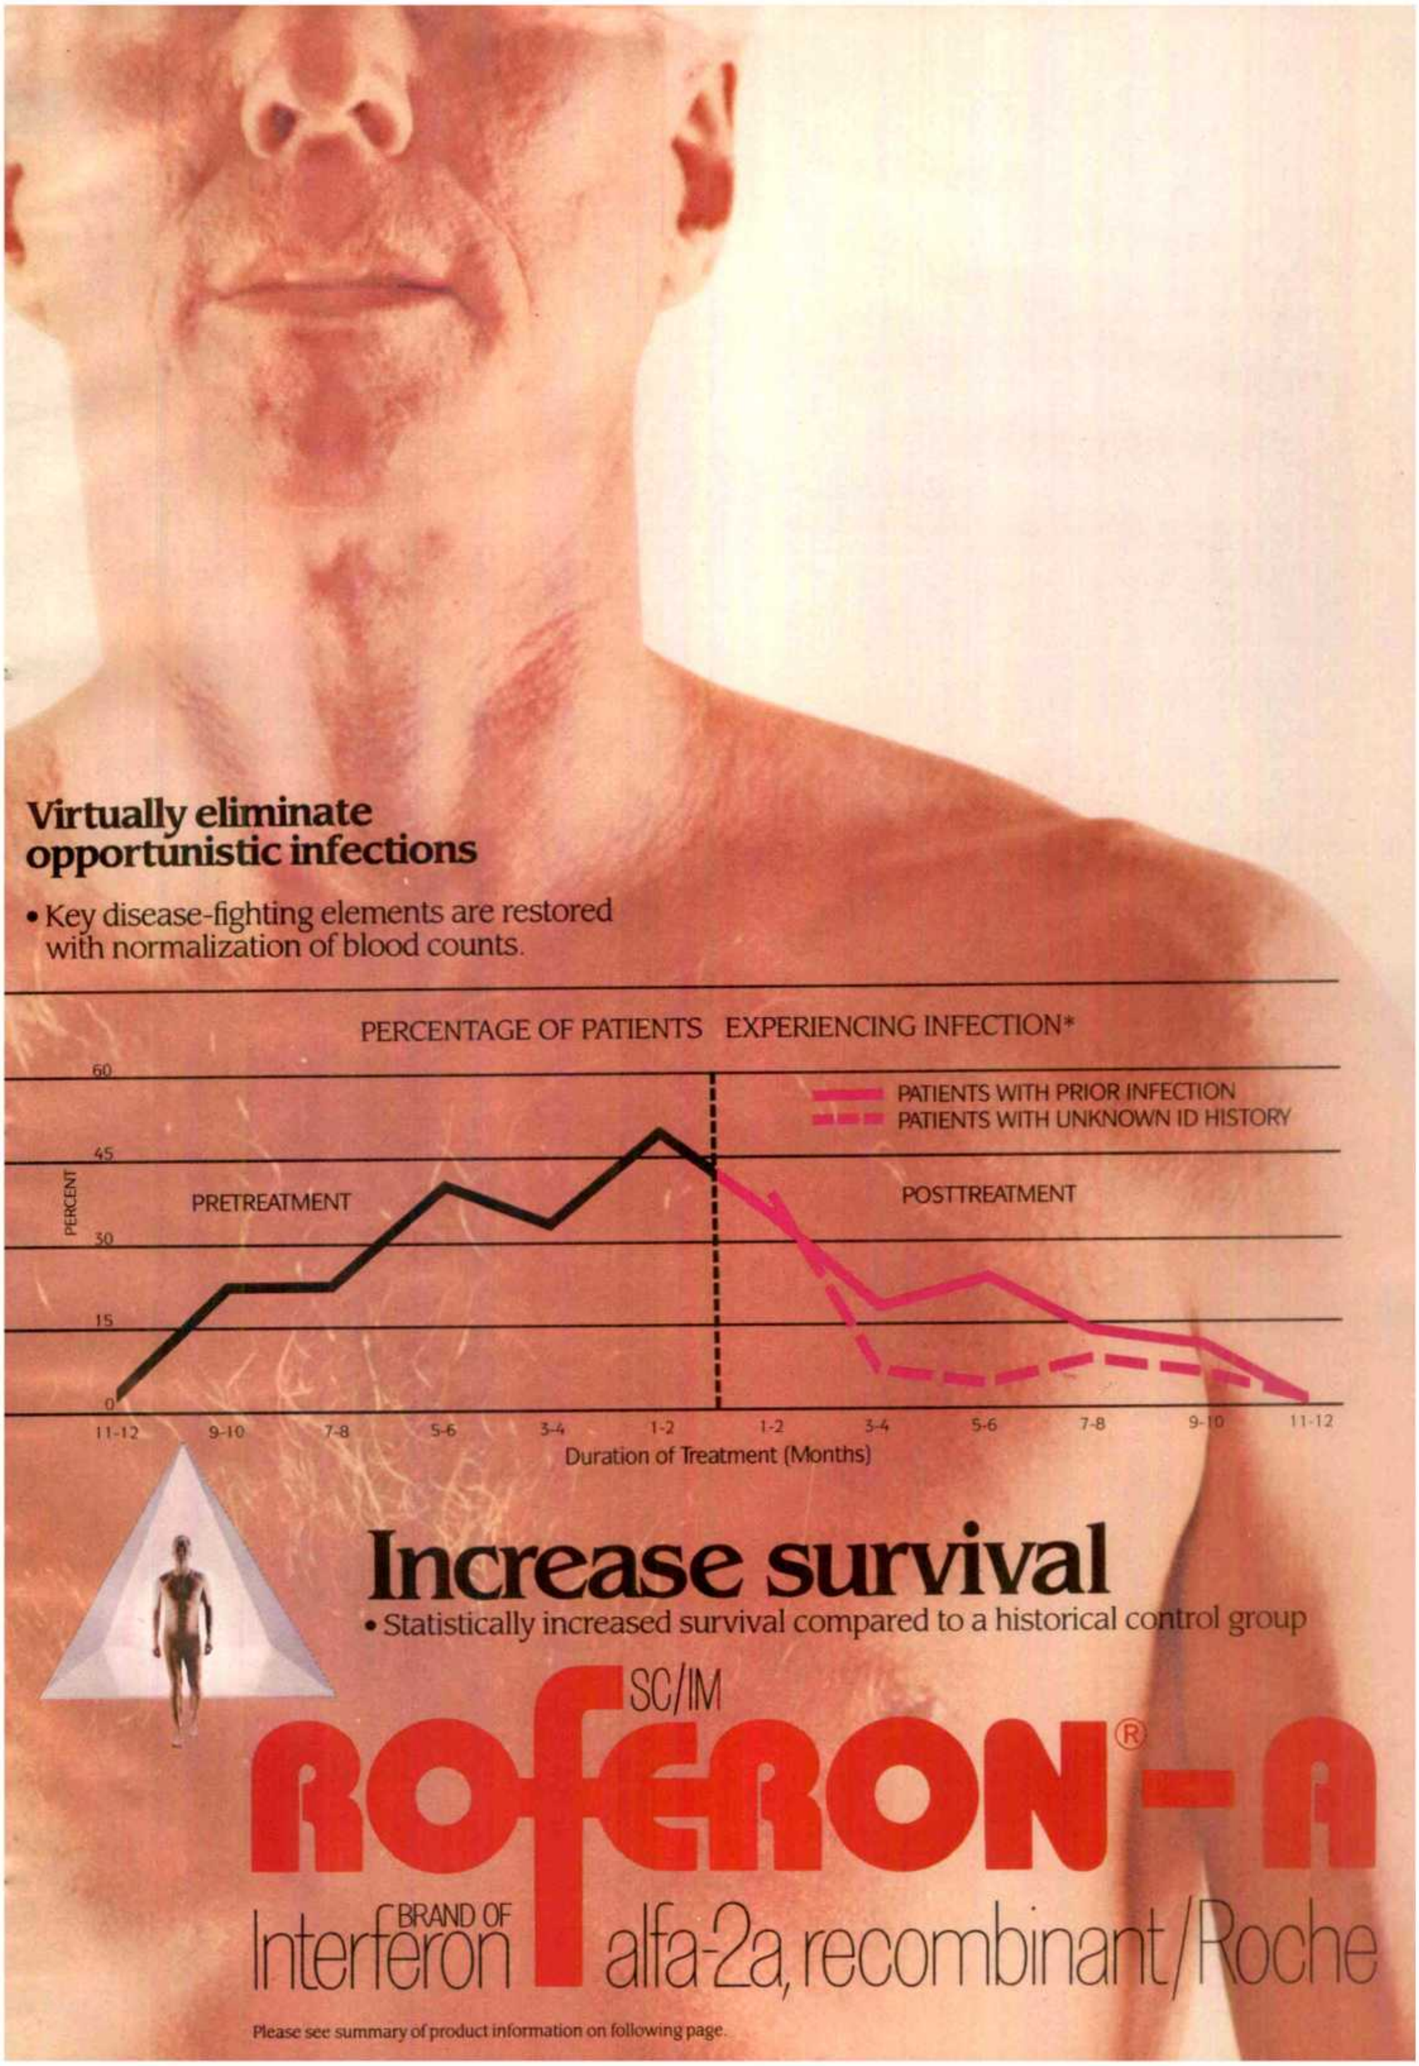
- As blood parameters normalize, there is a concurrent decrease in peripheral blood hairy cells.

The Roferon-A multicenter study consisted of 96 patients, all of whom were evaluated for safety. Seventy-five patients were evaluable for efficacy. Of these, 57 had prior splenectomy and 18 had not; many were pancytopenic and transfusion-dependent. Of the 21 patients not evaluable for efficacy, 16 were not on drug long enough for efficacy evaluation at the time of data analysis, 2 were removed for administrative reasons, and 3 were removed for preexisting intercurrent illness.

*Multicenter Study, Data on file, Hoffmann-La Roche Inc., Nutley, NJ.

ROCHE® Leading the way in biotherapeutics

Copyright © 1987 by Hoffmann-La Roche Inc. All rights reserved.



Virtually eliminate opportunistic infections

- Key disease-fighting elements are restored with normalization of blood counts.

Increase survival

- Statistically increased survival compared to a historical control group

SC/IM

ROFERON®-A

BRAND OF
Interferon alfa-2a, recombinant/Roche

Please see summary of product information on following page.

ROFERON®-A
Interferon alfa-2a, recombinant/Roche

Before prescribing, please consult complete product information, a summary of which follows:

CONTRAINDICATIONS: Hypersensitivity to alfa interferon, mouse immunoglobulin or any component of the product.

WARNINGS: Administer only under guidance of qualified physician. (See DOSAGE AND ADMINISTRATION.) Appropriate management of therapy and its complications is possible only when adequate diagnostic and treatment facilities are readily available.

Use with caution in patients with severe preexisting cardiac disease, severe renal or hepatic disease, seizure disorders and/or compromised CNS function.

Because of the possibility of severe or even fatal adverse reactions, inform patients of both benefits and risks.

Use with caution in patients with cardiac disease or *any* history of cardiac illness. No direct cardiotoxic effect has been demonstrated, but it is likely that acute, self-limited toxicities (*i.e.*, fever, chills) frequently associated with administration may exacerbate preexisting cardiac conditions. Rarely, myocardial infarction has occurred.

Exercise caution in administration to patients with myelosuppression.

CNS adverse reactions included decreased mental status, exaggerated CNS function, dizziness. More severe obtundation and coma rarely observed. Most of these abnormalities were mild and reversible within a few days to three weeks upon dose reduction or discontinuation of therapy. Careful periodic neuropsychiatric monitoring of all patients recommended.

Leukopenia and elevation of hepatic enzymes occurred frequently but were rarely dose-limiting. Thrombocytopenia occurred less frequently. Proteinuria and increased cells in urinary sediment were also seen infrequently. Rarely, significant hepatic, renal and myelosuppressive toxicities were noted.

PRECAUTIONS: *General:* When considering for chemotherapy, evaluate need and usefulness of the drug against risk of adverse reactions. Most adverse reactions are reversible if detected early. If severe reactions occur, reduce dosage or discontinue drug and take appropriate corrective measures. Reinstitute therapy with caution and with adequate consideration of the further need for the drug and alertness to possible recurrence of toxicity.

The minimum effective dose in hairy cell leukemia not established.

Information for Patient: Caution patients not to change brands of Interferon without medical consultation, as a change in dosage may result. Inform patients regarding potential benefits and risks. If home use is desirable, give instructions on appropriate use, including review of the Patient Information Sheet. Patients should be well hydrated, especially during initial stages of treatment.

Laboratory Tests: Complete blood counts and liver function tests should be performed prior to therapy and at appropriate periods during therapy. Since responses are not generally observed for one to three months after treatment initiation, very careful monitoring for severe depression of blood cell counts is warranted during the initial phase.

Patients who have preexisting cardiac abnormalities and/or are in advanced stages of cancer should have electrocardiograms taken prior to and during treatment.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Carcinogenesis: Roferon-A has not been tested for carcinogenic potential.

Mutagenesis: A. Internal studies. Ames test results revealed no evidence of mutagenicity. Human lymphocyte cultures were treated *in vitro* at noncytotoxic concentrations. No increase in chromosomal damage noted. B. Published studies. No published studies on mutagenic potential. However, a number of studies on the genotoxicity of human leukocyte interferon have been reported. A chromosomal defect has been reported after the addition of human leukocyte interferon to lymphocyte cultures from a patient suffering from a lymphoproliferative disorder. Other studies have failed to detect chromosomal abnormalities following treatment of lymphocyte cultures from healthy volunteers with human leukocyte interferon. Protection from chromosomal aberrations produced by gamma rays observed in primary chick embryo fibroblasts.

Impairment of Fertility: Nonpregnant female rhesus monkeys treated at doses of 5 and 25 million IU/kg/day have shown menstrual cycle irregularities, including prolonged or shortened menstrual periods and erratic bleeding; these cycles were considered to be anovulatory. Monkeys returned to a normal menstrual rhythm following discontinuation of treatment.

Drug Interactions: Not fully evaluated.

PREGNANCY: Pregnancy Category C. Safe use in human pregnancy not established. Therefore, use during pregnancy only if potential benefit justifies potential risk to fetus. Primate studies showed dose-related menstrual irregularities and an increased incidence of spontaneous abortions. Decreases in serum estradiol and progesterone concentrations reported in women treated with human leukocyte interferon. Therefore, fertile women should not receive Roferon-A unless they are using effective contraception during therapy. Male fertility and teratologic evaluations have yielded no significant adverse effects.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants, a decision should be made whether to discontinue nursing or the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children under 18 not established.

ADVERSE REACTIONS: The following data on adverse reactions are based on the SC or IM administration of Roferon-A as a single agent for the treatment of 63 patients with hairy cell leukemia during investigational trials in the U.S.

Flu-like syndromes consisting of fatigue (89%), fever (98%), chills (64%), myalgias (73%), headache (71%) occurred in the majority of patients and tended to diminish with continuing therapy. Other side effects such as anorexia (46%), nausea (32%), emesis (10%), diarrhea (29%), dizziness (21%), rash (18%), change in taste (13%), dryness or inflammation of the oropharynx (16%), dry skin or pruritus (13%), weight loss (14%) were observed with moderate frequency. Less commonly, diaphoresis (8%), paresthesias (6%), numbness (6%), partial alopecia (8%), reactivation of herpes labialis (8%), transient impotence (6%), arthralgias (5%) were also observed. Rarely (<3%), CNS effects including decreased mental status, depression, visual disturbances, sleep disturbances, nervousness, as well as cardiac adverse events, including hypertension, chest pain, arrhythmias, palpitations, were reported. Adverse experiences which occurred rarely and may have been related to underlying disease included epistaxis, bleeding gums, ecchymosis, petechiae. Miscellaneous adverse events, such as night sweats, urticaria, conjunctivitis, inflammation at the site of injection, were also rarely observed.

Roferon-A has also been evaluated for the treatment of many other types of cancer under investigation in the U.S. These studies generally utilized higher doses (12 to 50 million IU/m^2). All of the above adverse reactions which occurred in patients with hairy cell leukemia were also observed in patients receiving higher doses. The incidence of most adverse reactions was similar between the two groups, but tended to be more severe in the higher dosage group. Additional adverse effects which occurred in these patients included confusion (10%), hypotension (6%), lethargy (3%), edema (3%). Adverse experiences occurring in less than 1% of these patients and observed only in patients with malignancies other than hairy cell leukemia are as follows: *GI:* abdominal fullness, hypermotility, hepatitis; *CNS:* gait disturbance, poor coordination, hallucinations, syncope, seizures, encephalopathy, psychomotor retardation, coma, stroke, transient ischemic attacks, aphasia, aphonia, dysarthria, dysphasia, forgetfulness, amnesia, sedation, apathy, anxiety, emotional lability, irritability, hyperactivity, involuntary movements, claustrophobia, loss of libido; *Peripheral Nervous System:* muscle contractions; *Cardiovascular:* congestive heart failure, pulmonary edema, myocardial infarction, Raynaud's phenomenon, hot flashes; *Pulmonary:* bronchospasm, tachypnea; *Miscellaneous:* excessive salivation, flushing of skin.

Abnormal Laboratory Test Values: The percentages of abnormal laboratory test values seen in 1019 patients evaluated in overall safety trials (including hairy cell leukemia patients) are: *Hematologic:* leukopenia (69%), neutropenia (58%), thrombocytopenia (42%), decreased hemoglobin (6.3%), decreased hematocrit (12.5%); mean time to nadir: WBC—22 days, platelets—17 days. *Hepatic:* SGOT (78%), alkaline phosphatase (48%), LDH (47%), bilirubin (31%). *Renal/Urinary:* BUN (10%), serum creatinine (10%), uric acid (15%), proteinuria (25%). *Other Tests:* hypocalcemia (51%), elevated serum glucose (39%), elevated serum phosphorus (17%).

Neutralizing antibodies were detected in approximately 27% of all patients (3.4% for hairy cell leukemia patients). No clinical sequelae of their presence have been documented. Antibodies may occur spontaneously in certain clinical conditions.

DOSAGE AND ADMINISTRATION: Hairy Cell Leukemia—The dose of Roferon-A is 3 million IU daily for 16 to 24 weeks, administered as an SC or IM injection. SC administration is particularly advisable for, but not limited to, thrombocytopenic patients (platelet count <50,000) or for patients at risk for bleeding. The recommended maintenance dose is 3 million IU, 3 times/week. Dosage reduction by one-half or withholding of individual doses may be needed when severe adverse reactions occur. The use of doses higher than 3 million IU is not recommended. Treatment should be continued for 6 months before determining whether to discontinue therapy in nonresponding patients. The optimal duration of treatment has not been determined in responding patients. If severe reactions occur, modify dosage (50% reduction) or temporarily discontinue therapy until adverse reactions abate. The need for dosage reduction should take into account the effects of prior X-ray therapy or chemotherapy that may have compromised bone marrow reserve.

HOW SUPPLIED: Roferon-A Injectable Solution: Vials containing 3 million IU Interferon alfa-2a, recombinant/Roche (3 million IU/mL). Boxes of 10 (NDC 0004-1987-01). Roferon-A Injectable Solution: Vials containing 18 million IU Interferon alfa-2a, recombinant/Roche (3 million IU/0.5 mL). Boxes of 1 (NDC 0004-1988-09). Roferon-A Sterile Powder for Injection: Vials containing 18 million IU Interferon alfa-2a, recombinant/Roche, with accompanying diluent. Boxes of 1 (NDC 0004-1993-09). For reconstitution, storage and handling directions, see complete product information.

P.I. 1086

The promise fulfilled

Restore quality to life

- Performance status greatly improved
- 86% of patients gained up to 10% of, or maintained, their total body weight

Common side effects usually self-limiting and manageable

Initial side effects, such as fever, chills, myalgias, headache and fatigue, are self-limiting and generally manageable. Myelosuppression, which can occur early in the treatment course, warrants close clinical and laboratory observation and is usually alleviated by dose reduction or temporary discontinuation of drug. Roferon-A should be used with caution in patients with severe preexisting cardiac disease, severe renal or hepatic disease, seizure disorders and/or compromised central nervous system function. Persistent fatigue is found to be less troublesome with *p.m.* or *h.s.* administration.

SC/IM fixed dosing simple enough for self-administration

Ready-to-Use Injectable Solution

No mixing or reconstitution necessary

3 million IU vial (3 million IU/mL)

18 million IU vial (3 million IU/0.5 mL)

Sterile Powder for Injection

18 million IU vial (3 million IU/0.5 mL)

3 mL diluent for reconstitution

Must be refrigerated at temperatures of 36° to 46°F (2° to 8°C). At no time should Roferon-A Ready-to-Use Injectable Solution remain unrefrigerated for more than 24 hours. The Sterile Powder for Injection should not remain unrefrigerated for more than 48 hours. Once the powder is reconstituted, it should be refrigerated and must be used within 30 days. Do not freeze or shake.

SC/IM

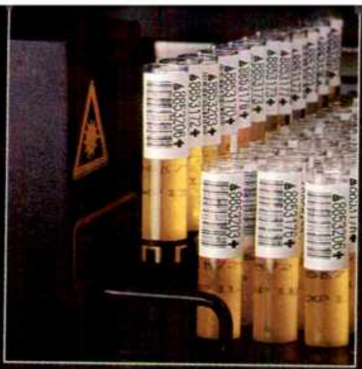
ROFERON®-A

Interferon BRAND OF alfa-2a, recombinant/Roche

The fourth modality

Please see summary of product information on adjacent page.

Robotic arm holds up to 12 disposable, miniature, syringe-like tips. Each tip has a liquid level sensor for error-free sampling.



For positive I.D., the integrated barcode system reads labels on both tubes and plates, and correlates the data.

Graphic-aided software gives you flexibility and control to perform multiple tasks and methods. Pipetting sequences are displayed on the monitor and can be run, reviewed or changed.

THE NEW MICROLAB® AT. BECAUSE SAMPLE PREP SHOULDN'T TEST YOUR PATIENCE.

Whether you're a blood bank, or large clinical or research lab, you know that sample prep and reagent transfers are both time consuming and prone to error. In fact, over 50% of the labor in ELISA and other microwell plate assays is consumed in just getting samples ready. What's worse, any attempt to increase throughput usually means a decrease in accuracy and precision.

Unless you have a new Hamilton Microlab AT.

The Microlab AT is an automated, multi-tasking sample prep system that performs everything from serial dilutions to multiple transfer operations such as sample to plate, reagent to plate, plate to plate, sample plus reagent to plate and plate to waste. And that's not all!

The Microlab AT's high-speed robotic arm features 12 miniature, positive displacement tips that are washable and reusable. The tips can mix, dilute and/or add reagents. The robotic arm is fast, too, transferring up to 96 samples from tubes to plates in under four minutes, or 1,200 samples per hour.

Plus, the integrated bar code system scans both tubes and plates to provide 100% positive I.D. while pipetting.

It must be hard to use, right? On the contrary, it's easy. And flexible. Using your IBM or compatible computer with our unique software, a few keystrokes will help you create methods for virtually any testing application now, and in the future.

So if sample prep is testing your patience, then the Microlab AT is just what you've been waiting for. Send for a free brochure, Call (800) 648-5950 or (702) 786-7077. Or write Hamilton Company, P.O. Box 10030, Reno, Nevada 89520.

HAMILTON
The measure of excellence

Be Immortal.

If you could look into the eyes of generations yet to come, you would be there.

Because immortality lies not in the things you leave behind, but in the people that your life has touched, for good or bad.

By including the American Cancer Society in your will, you can have a powerful effect on those who come after you.

You see, cancer *is* beatable. The survival rate for all cancers is already approaching 50% in the United States.

You'll be leaving behind a legacy of life for others. And that is a beautiful way of living forever yourself.

AMERICAN CANCER SOCIETY®

For more information, call your local ACS unit or write to the American Cancer Society, 4 West 35th Street, New York, NY 10001.

TWO-COLOR ANALYSIS: COULTER HAS THE SOLUTION.

Our four new dual assays are ideal for reducing preparation and analysis time for screening panels in lymphocyte phenotyping. Selected combinations of monoclonal antibodies offer the maximum in clinical relevance, ease of use, and cost savings. We have available combinations for enumeration of T and B cells, helper/suppressor cells, helper cell subsets, and T3/I3 for the identification of states of T lymphocyte activation.

- **OPTIMAL FORMULATIONS:** Proprietary manufacturing techniques yield clean results with little or no background.
- **CLINICALLY RELEVANT COMBINATIONS:** These particular dual color assays offer the most clinically relevant combinations.
- **MAJOR TIME SAVINGS:** Dual assays reduce overall technical labor time by half.
- **READY TO USE:** No centrifugation required for these liquid reagents, optimally titered and conjugated.

To order, call 1-800-327-3778 or 1-800-432-6518, Ext. 6880 from Florida.

RETROVIR®

(zidovudine)

Helps patients live longer, live better

New England Journal of Medicine reports

"[RETROVIR] AZT administration was therefore associated with a fourfold-to-sixfold reduction in the mortality rates in the study population at nine months."[1]

Patients live longer

A 90% survival rate was reported for AIDS and ARC patients treated with RETROVIR after one year— *v* 50% in a similar group of untreated patients[1,2]

Patients live better

Improves patients' general health and quality of life[1]

- Significantly reduces symptoms related to HIV infection
- Many patients can resume productive lives
- Reduces risk and severity of opportunistic infections
- Improves immune status

Improves patients' cognitive status[3,4]

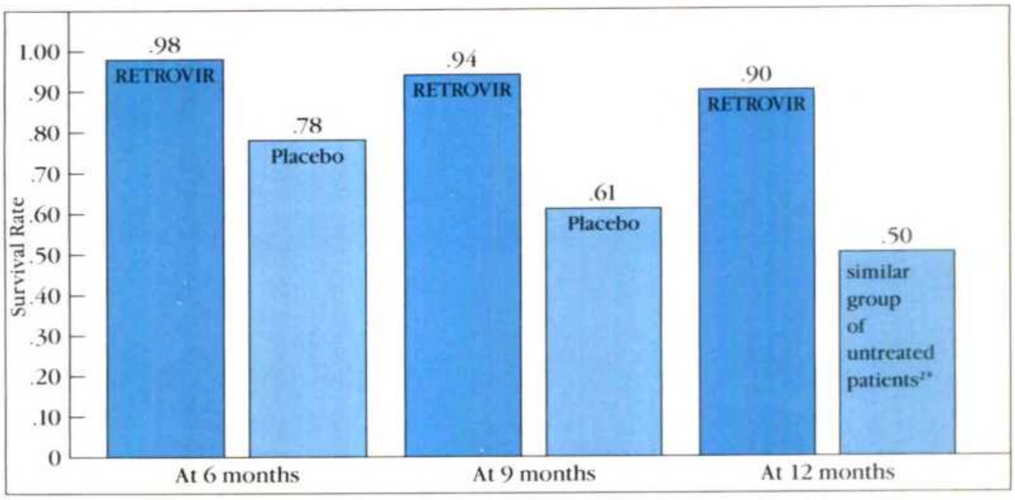
- Produced statistically significant improvements in long-term memory, motor function, concentration, and information-processing ability
- RETROVIR crosses the blood-brain barrier

IMPROVING LIVES THROUGH
ANTIVIRAL RESEARCH

BURROUGHS WELLCOME CO

Helps patients live longer

Survival rates for AIDS/ARC patients combined at 6, 9, and 12 months[1,2]

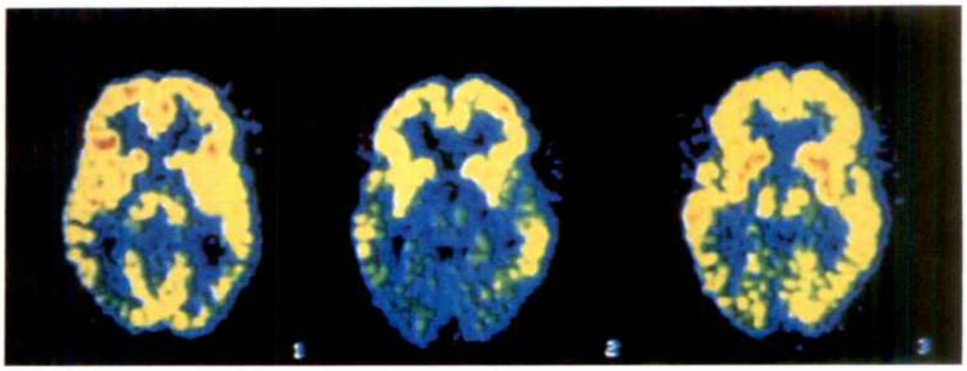


*Extrapolated from data of the Centers for Disease Control: *Morbidity and Mortality Weekly Report.*

Helps patients live better

Improvement following RETROVIR therapy demonstrated by positron emission tomography[3]

PET scans of normal control (1) and patient with HIV-related neuropathy and dementia before (2) and after (3) 13 weeks of RETROVIR therapy



Normal control (1)

Patient before RETROVIR therapy (2)

Patient following RETROVIR therapy (3)

A homogeneous pattern of glucose metabolism can be seen in the normal control (1) as compared with the heterogeneous pattern in the patient prior to RETROVIR therapy (2). After 13 weeks of treatment, the abnormal pattern has partly resolved (3).

Guidelines for successful management

- RETROVIR therapy is generally well tolerated by many patients, particularly those with higher T4 cell counts and more intact bone marrow function at the start of therapy
- Hematologic monitoring is recommended every two weeks; there is a possibility of bone marrow toxicity and subsequent RBC and WBC depression
- Concomitant use of acetaminophen with RETROVIR may potentiate granulocytopenia; other drugs that may interfere with RETROVIR metabolism should be avoided.

Please see brief summary of prescribing information on last page of this advertisement.

RETROVIR® (ZIDOVUDINE) Capsules

WARNING: THERAPY WITH RETROVIR (ZIDOVUDINE) IS OFTEN ASSOCIATED WITH HEMATOLOGIC TOXICITY INCLUDING GRANULOCYTOPENIA AND SEVERE ANEMIA REQUIRING TRANSFUSIONS (SEE WARNINGS).

IN ADDITION, PATIENTS TREATED WITH ZIDOVUDINE MAY CONTINUE TO DEVELOP OPPORTUNISTIC INFECTIONS (OI'S) AND OTHER COMPLICATIONS OF THE ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) AND AIDS RELATED COMPLEX (ARC) CAUSED BY THE HUMAN IMMUNODEFICIENCY VIRUS (HIV). THEREFORE, PATIENTS ON ZIDOVUDINE SHOULD BE UNDER CLOSE CLINICAL OBSERVATION BY PHYSICIANS EXPERIENCED IN THE TREATMENT OF PATIENTS WITH DISEASES ASSOCIATED WITH HIV. THE SAFETY AND EFFICACY OF ZIDOVUDINE HAVE BEEN ESTABLISHED ONLY FOR CERTAIN ADULT AIDS AND ADVANCED ARC PATIENTS (SEE "INDICATIONS AND USAGE").

INDICATIONS AND USAGE: Retrovir Capsules are indicated for the management of certain adult patients with symptomatic HIV infection (AIDS and advanced ARC) who have a history of cytologically confirmed *Pneumocystis carinii* pneumonia (PCP) or an absolute CD4 (T4 helper/inducer) lymphocyte count of less than 200/mm^3 in the peripheral blood before therapy is begun.

This indication is based primarily on the results of a randomized, double-blind, placebo-controlled trial conducted at 12 medical centers in the United States in which 281 patients with AIDS or advanced ARC were studied for an average of four and a half months. Additional data have been collected on approximately 80% of these patients who have received zidovudine in an open-label extension of this trial for an average of five more months.

The patient population of the controlled trial consisted of 160 AIDS patients (85 Retrovir and 75 placebo) who had recovered from their first episode of PCP diagnosed within the previous four months, and 121 ARC patients (59 Retrovir and 62 placebo) with multiple signs and symptoms of HIV infection, including mucocutaneous candidiasis and/or unexplained weight loss ($\geq$ 15 lbs or $>$ 10% of prior body weight). All patients had evidence of impaired cellular immunity with an absence of delayed cutaneous hypersensitivity and a decreased number of CD4 (T4) lymphocytes in the peripheral circulation. Two hundred twenty-one (79% of all patients) had fewer than 200 T4 cells/mm^3 at entry (95% of AIDS patients and 57% of ARC patients). All patients began therapy at a dose of 250 mg every 4 hours around the clock. This dosage was reduced or temporarily or permanently discontinued if serious marrow toxicity occurred. The trial was stopped because of a significant reduction in mortality before all patients had completed the planned 24 weeks of treatment. There were 19 deaths in the placebo group and 1 in the Retrovir group ($p < .001$). All deaths were apparently due to opportunistic infections (OI) or other complications of HIV infection. Treatment duration ranged from 12 weeks to 26 weeks, with a mean and median duration of 17 and 18 weeks, respectively.

Retrovir also significantly reduced the risk of acquiring an AIDS-defining OI in patients after 6 weeks of treatment ($p < .001$). In addition, patients who received Retrovir generally did better than the placebo group in terms of several other measures of efficacy including performance level, neuropsychiatric function, maintenance of body weight and the number and severity of symptoms associated with HIV infection. A modest increase in mean CD4 (T4) counts was seen in the zidovudine group but the significance of this finding is unclear as the CD4 (T4) counts declined again in some patients.

The most significant adverse reaction noted in the study was a depression of formed elements in the peripheral blood, which necessitated dose reduction or drug discontinuation in 49 of the 144 (34%) patients receiving Retrovir. Of those participants whose baseline CD4 (T4) lymphocyte counts were less than 200, 47% of those receiving Retrovir and 10% of those receiving placebo developed a granulocyte count of $<$750/mm^3. Similarly, 45% of Retrovir recipients and only 14% of placebo recipients had a 25% or greater reduction in hemoglobin. (See ADVERSE REACTIONS.)

At the conclusion of the placebo-controlled trial, 127 Retrovir recipients and 100 placebo recipients elected to enroll in an uncontrolled extension protocol in which all patients received Retrovir at a dose of 200 mg every four hours. This dose was chosen because of concern about cumulative hematologic toxicity and to allow for greater flexibility in dosing. Over the subsequent five months, opportunistic infections continued to occur and additional patients died in both groups. Sixteen patients from the original placebo cohort died after the conclusion of the controlled trial. Four of these 16 never received Retrovir and seven expired during the first month of therapy. Ten additional deaths occurred among the original Retrovir recipients. With respect to these data, termination of the controlled trial precludes direct comparisons of mortality and morbidity between the original placebo and drug recipients. Long-term follow-up of these patients, however, will allow for examination of the natural history of prolonged zidovudine therapy.

CONTRAINDICATIONS: Retrovir Capsules are contraindicated for patients who have potentially life-threatening allergic reactions to any of the components of the formulation.

WARNINGS: Zidovudine has been carefully studied in limited numbers of seriously ill HIV-infected patients treated for a limited period of time. Therefore, the full safety and efficacy profile of zidovudine has not been completely defined, particularly in regard to prolonged use, and especially in HIV-infected individuals who have less advanced disease.

Zidovudine should be used with extreme caution in patients who have bone marrow compromise evidenced by granulocyte count $<$ 1000/mm^3 or hemoglobin $<$ 9.5 g/dl. In the placebo-controlled study, anemia and granulocytopenia were the most significant adverse events observed (see ADVERSE REACTIONS).

Significant anemia most commonly occurred after 4 to 6 weeks of therapy and in many cases required dose adjustment, discontinuation of zidovudine, and/or blood transfusions. Frequent (at least every 2 weeks) blood counts are strongly recommended in patients taking zidovudine. If anemia or granulocytopenia develops, dosage adjustments may be necessary (see DOSAGE AND ADMINISTRATION).

Coadministration of zidovudine with other drugs metabolized by glucuronidation should be avoided because the toxicity of either drug may be potentiated (see Drug Interactions under PRECAUTIONS). Zidovudine recipients who used acetaminophen during the controlled trial had an increased incidence of granulocytopenia which appeared to be correlated with the duration of acetaminophen use.

PRECAUTIONS:

General: Zidovudine is eliminated from the body primarily by renal excretion following metabolism in the liver (glucuronidation). There are currently no data available concerning the use of zidovudine in patients with impaired renal or hepatic function, and such patients may be at a greater risk of toxicity from zidovudine.

Drug Interactions: The interaction of other drugs with zidovudine has not been studied in a systematic manner. Coadministration of zidovudine with drugs that are nephrotoxic, cytotoxic, or which interfere with RBC/WBC number or function (e.g., dapsone, pentamidine, amphotericin B, flucytosine, vincristine, vinblastine, adriamycin, or interferon) may increase the risk of toxicity. Limited data suggest that probenecid may inhibit glucuronidation and/or reduce renal excretion of zidovudine. In addition, other drugs (e.g., acetaminophen, aspirin, or indomethacin) may competitively inhibit glucuronidation (see WARNINGS).

Some experimental nucleoside analogues which are being evaluated in AIDS and ARC patients may affect RBC/WBC number or function and may increase the potential for hematologic toxicity of zidovudine. Some experimental nucleoside analogues affecting DNA replication antagonize the *in vitro* antiviral activity of zidovudine against HIV and thus, concomitant use of such drugs should be avoided.

Some drugs such as trimethoprim-sulfamethoxazole, pyrimethamine, and acyclovir may be necessary for the management or prevention of opportunistic infections. In the controlled trial, increased toxicity was not detected with limited exposure to these drugs. However, there are two published reports of neurotoxicity (one of profound lethargy and one of seizure) associated with concomitant use of zidovudine and acyclovir.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies of zidovudine in animals have not been completed. However, in an *in vitro* mammalian cell transformation assay, zidovudine was positive at concentrations of 0.5 μg/ml and higher.

No evidence of mutagenicity (with or without metabolic activation) was observed in the Ames *Salmonella* mutagenicity assay. In a mutagenicity assay conducted in L5178Y/TK$^{+/-}$ mouse lymphoma cells, zidovudine was weakly mutagenic in the absence of metabolic activation only at the highest concentrations tested (4000 and 5000 μg/ml). In the presence of metabolic activation, the drug was weakly mutagenic at concentrations of 1000 μg/ml and higher. In an *in vitro* cytogenetic study performed in cultured human lymphocytes, zidovudine induced dose-related structural chromosomal abnormalities at concentrations of 3 μg/ml and higher. No such effects were noted at the two lowest concentrations tested, 0.3 and 1 μg/ml.

Pregnancy: Pregnancy Category C. An oral teratology study in pregnant rats using doses up to 20 times the human dose has revealed no evidence of harm to the fetus due to zidovudine. It is not known whether zidovudine can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Zidovudine should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether zidovudine is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions from zidovudine in nursing infants, mothers should be instructed to discontinue nursing if they are receiving zidovudine.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequent adverse events and abnormal laboratory values reported in the placebo-controlled clinical trial of oral zidovudine administration in 281 patients (144 patients zidovudine; 137 patients placebo) were granulocytopenia and anemia. The occurrence of these hematologic toxicities was inversely related to CD4 (T4) lymphocyte number, hemoglobin, and granulocyte count at study entry, and directly related to dose and duration of therapy. The frequency of granulocytopenia and anemia according to the patients' CD4 (T4) levels is shown in the following table:

	Pretreatment CD4 (T4) Levels			
	≤200/mm^3		>200/mm^3	
Abnormality	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia ($<$ 750/mm^3)	47%	10%	10%	3%
Anemia (Hgb $<$7.5 g/dl)	30%	6%	3%	0%

Because many patients were anemic and/or granulocytopenic before starting therapy with zidovudine, examining the degree of change when compared to baseline, as shown in the table below, may be more informative.

		Pretreatment CD4 (T4) Levels			
		≤200/mm^3		>200/mm^3	
Abnormality	% Decrease from Baseline	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia	>50%	55%	19%	40%	13%
Anemia	>25%	45%	14%	10%	10%

The anemia appeared to be the result of impaired erythrocyte maturation as evidenced by increasing macrocytosis (MCV) while on drug.

The 281 patients treated in this controlled trial had serious underlying disease with multiple baseline symptoms and clinical abnormalities. The following table summarizes those reported clinical adverse events which occurred in at least 5% of all patients treated with zidovudine. Severe headache, nausea, insomnia and myalgia were reported at a significantly greater rate in zidovudine recipients.

Percentage (%) of Patients with Clinical Events					
Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %	Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %
BODY AS A WHOLE			MUSCULOSKELETAL		
Asthenia	19	18	Myalgia	8	2
Diaphoresis	5	4	NERVOUS		
Fever	16	12	Dizziness	6	4
Headache	42	37	Insomnia	5	1
Malaise	8	7	Paresthesia	6	3
GASTROINTESTINAL			Somnolence	8	9
Anorexia	11	8	RESPIRATORY		
Diarrhea	12	18	Dyspnea	5	3
Dyspepsia	5	4	SKIN		
GI Pain	20	19	Rash	17	15
Nausea	46	18	SPECIAL SENSES		
Vomiting	6	3	Taste Perversion	5	8

Clinical adverse events which occurred in less than 5% of all patients treated with zidovudine are listed below. Since many of these adverse events were seen in placebo-treated patients as well as zidovudine recipients, they may not be attributable to the drug.

Body as a whole: body odor, chills, edema of the lip, flu syndrome, hyperalgesia, back pain, chest pain, lymphadenopathy.

Cardiovascular: vasodilation.

Gastrointestinal: constipation, dysphagia, edema of the tongue, eructation, flatulence, bleeding gums, rectal hemorrhage, mouth ulcer.

Musculoskeletal: arthralgia, muscle spasm, tremor, twitch.

Nervous: anxiety, confusion, depression, emotional lability, nervousness, syncope, loss of mental acuity, vertigo.

Respiratory: cough, epistaxis, pharyngitis, rhinitis, sinusitis, hoarseness.

Skin: acne, pruritus, urticaria.

Special senses: amblyopia, hearing loss, photophobia.

Urogenital: dysuria, polyuria, urinary frequency, urinary hesitancy.

DOSAGE AND ADMINISTRATION: The recommended starting dose of Retrovir (zidovudine) is 200 mg (two 100 mg capsules) administered orally every four hours around the clock.

Hematologic toxicities appear to be related to pretreatment bone marrow reserve and to dose and duration of therapy. Careful monitoring of hematologic indices every two weeks is recommended to detect serious anemia or granulocytopenia. In patients with hematologic toxicity, reduction in hemoglobin may occur as early as 2 to 4 weeks, and granulocytopenia usually occurs after 6 to 8 weeks.

Dose Adjustment: Significant anemia (hemoglobin of $<$ 7.5 g/dL or reduction of $>$25% of baseline) and/or significant granulocytopenia (granulocyte count of $<$750/mm^3 or reduction of $>$50% from baseline) may require a dose interruption until some evidence of marrow recovery is observed. For less severe anemia or granulocytopenia, a reduction in daily dose may be adequate. In patients who develop significant anemia, dose modification does not necessarily eliminate the need for transfusion. If marrow recovery occurs following dose modification, gradual increases in dose may be appropriate depending on hematologic indices and patient tolerance.

Formation of B-lymphocytes and other blood cells in tissue.

For ITP Patients

GAMIMUNE® N
Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

For patients with acute and chronic idiopathic thrombocytopenic purpura (ITP), maintaining normal platelet levels may be a life-threatening problem. They often need fast, aggressive therapy that will elevate platelet counts rapidly. They need Gamimune® N.

IGIV treatment with Gamimune® N may effect a therapeutic increase in platelets in both children and adults with ITP and, in some cases, allows the possibility of major surgery.[1] In one study,[1] 62.5% (10 of 16) adult patients and 83.3% (5 of 6) pediatric patients demonstrated a substantial response to an initial course of therapy with Gamimune® N.*†

Gamimune® N contains at least 98% gamma globulin and is the only ready-to-use liquid IGIV available. Cutter's patented fractionation method (based on Cohn-Oncley methods 6 and 9) assures Gamimune® N contains no heterologous proteins, with no detectable levels of protein aggregates or vasoactive enzymes.[2] And studies show *in vitro* inactivation of HIV (HTLV-III virus‡ during production of Gamimune® N.

Gamimune® N. Enhancing the natural process with fast, aggressive therapy for ITP in both children and adults.

---

*It is not possible to predict which patients with ITP will respond to therapy.

†In patients who respond to therapy, a rise in platelet count is generally rapid (within one to five days), transient (most often lasting from several days to several weeks), and should not be considered curative.

‡The Cohn-Oncley process used to produce Gamimune® N has been challenged *in vitro* with a virus spike of 1×10^5 TCID (Tissue Culture Infectious Doses) of HIV (HTLV-III) and found to remove and/or inactivate the viral challenge. In addition, Gamimune® N undergoes an incubation step as a final container which has been shown to effect an additional 1×10^3 to 1×10^4 reduction TCID (Tissue Culture Infectious Doses) of HIV (HTLV-III).[3]

GAMIMUNE® N
Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune® N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune® N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The in vivo half-life of Gamimune® N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N is 16.5 mEq/L (~ 0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune® N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune® N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune® N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune® N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune® N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune® N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune® N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune® N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune® N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune® N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune® N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune® N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune® N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PL^{A1} alloimmune antibody with platelet anti PL^{A1} specificity) also responded to treatment with Gamimune® N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N should be considered; in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1–5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune® N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune® N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune® N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune® N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune® N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune® N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune® N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune® N. It is not known whether Gamimune® N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune® N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune® N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune® N. Symptoms reported with Gamimune® N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N at the infusion site was reported in some cases.

In further studies of Gamimune® N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune® N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune® N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune® N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune® N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune® N for prophylaxis in immunodeficiency syndromes is 100–200 mg/kg (2–4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune® N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune® N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune® N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune® N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes; if well tolerated, the rate may be **gradually** increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

Chromogenics You Can Count On

The reasons your lab should use KabiVitrum chromogenics are as simple as 1 2 3...

The First

The substrates you've been using all along were developed first by KabiVitrum. They pioneered the development of synthetic chromogenic substrates 10 years ago, and revolutionized the investigation of coagulation and fibrinolysis proteins. Years of experience enables KabiVitrum to produce the highest quality substrates available.

The Most

KabiVitrum's extensive product line ranges from S-2251 — the most widely used substrate in the world — to new products for tissue plasminogen activator and inhibitor assays. As exclusive U.S. distributor of KabiVitrum products, Helena provides immediate shipment of your order from our Texas headquarters. And we back these products with solid support from our customer service group.

The Best

KabiVitrum is committed to continued development of new substrates. Some of the new substrates available are S-2366, for activated protein C and Factor XIa; and thrombin inhibitor, I-2581. Soon you can expect substrates for α_2-macroglobulin, and α_1-antitrypsin.

Call for your free KabiVitrum catalog, or to place an order. Toll free U.S.A. 800-231-5663.
In Texas, 800-392-3126.

In Alaska, Hawaii and Puerto Rico, 800-231-4678.

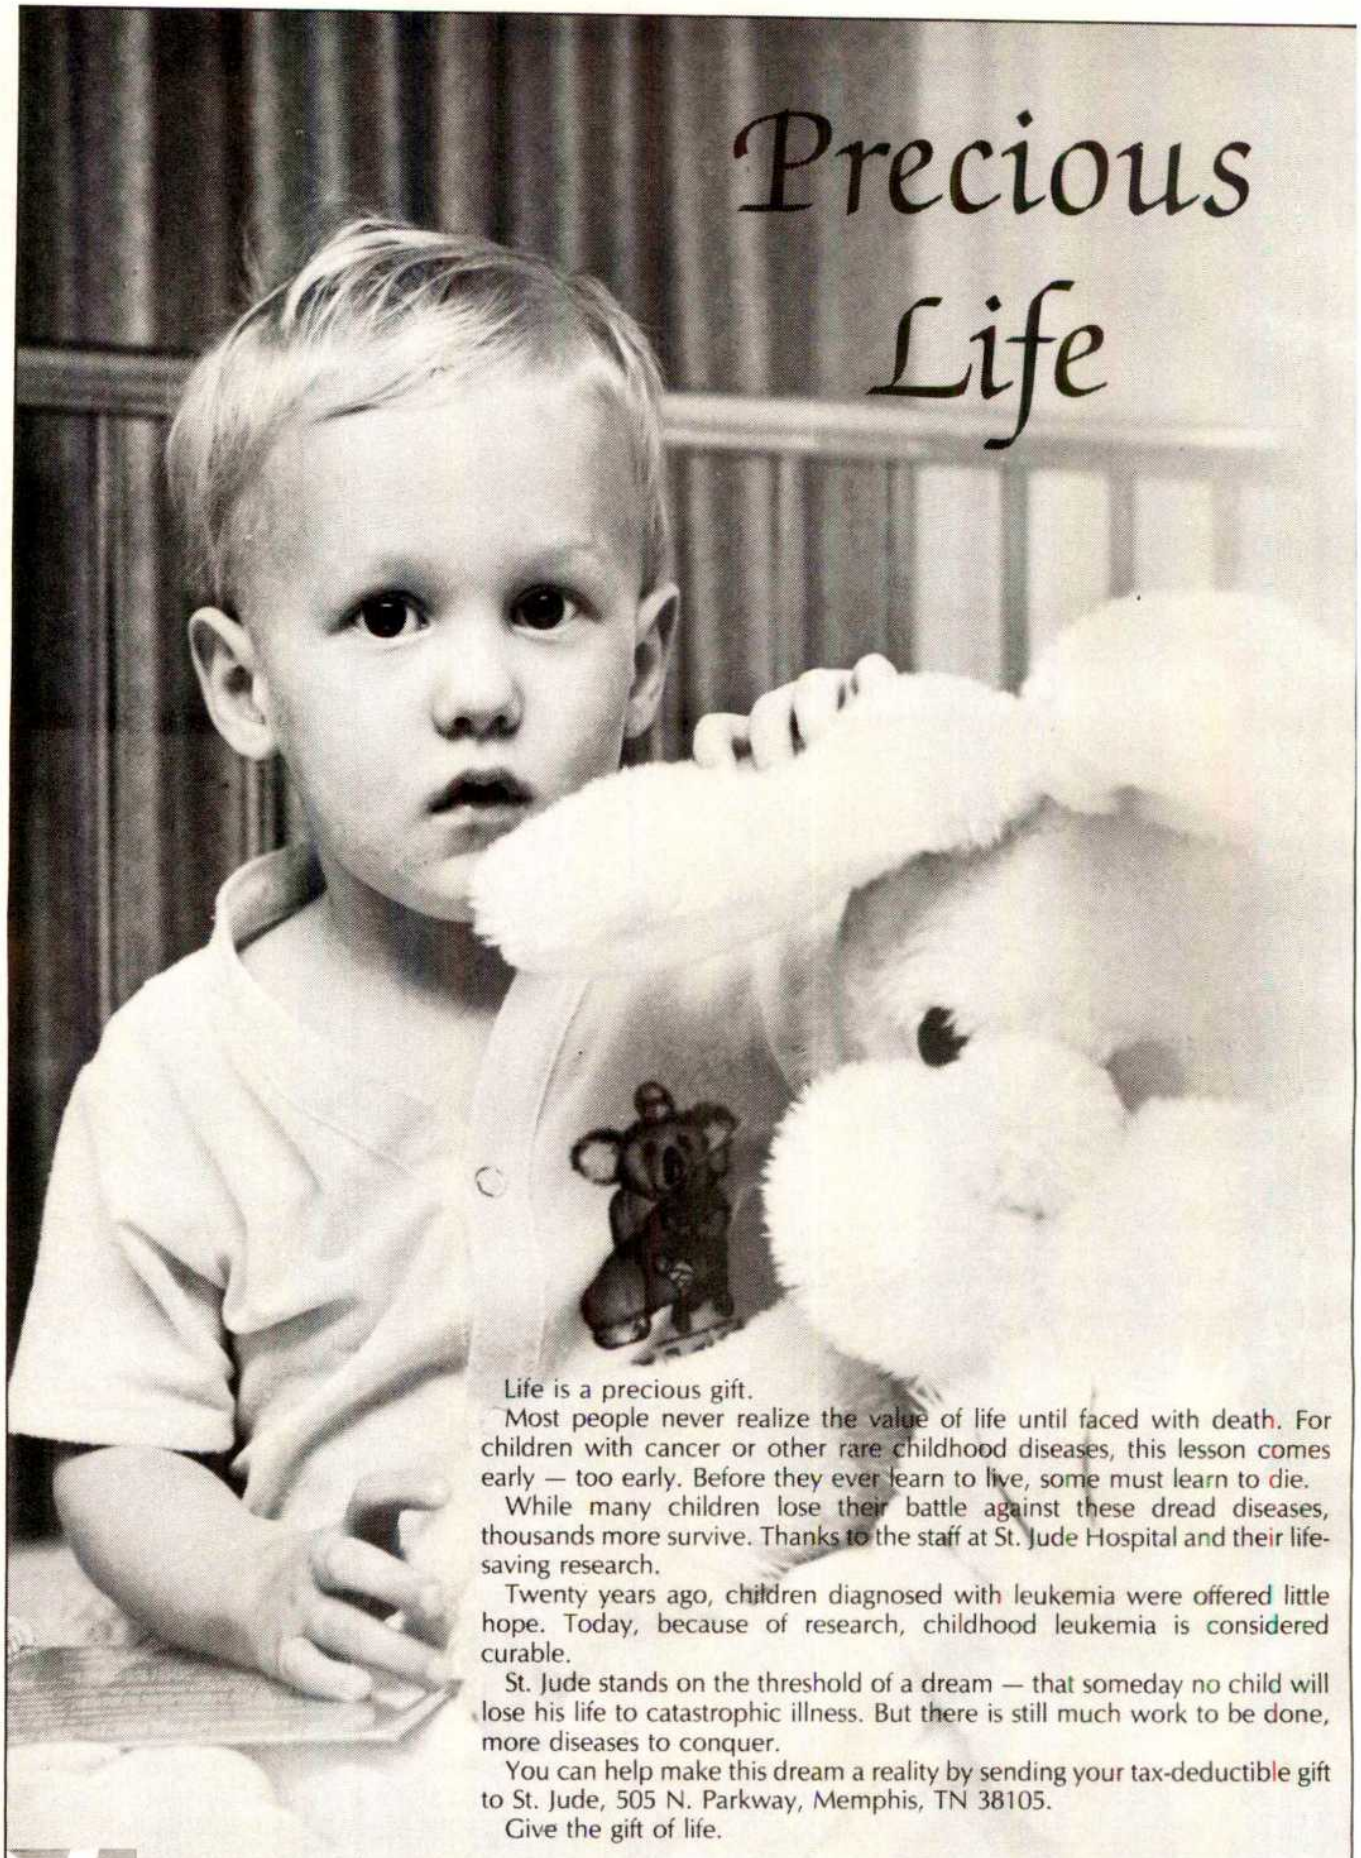
Hemostasis Systems

HELENA HAS THE ANSWERS



Life is a precious gift.

Most people never realize the value of life until faced with death. For children with cancer or other rare childhood diseases, this lesson comes early — too early. Before they ever learn to live, some must learn to die.

While many children lose their battle against these dread diseases, thousands more survive. Thanks to the staff at St. Jude Hospital and their life-saving research.

Twenty years ago, children diagnosed with leukemia were offered little hope. Today, because of research, childhood leukemia is considered curable.

St. Jude stands on the threshold of a dream — that someday no child will lose his life to catastrophic illness. But there is still much work to be done, more diseases to conquer.

You can help make this dream a reality by sending your tax-deductible gift to St. Jude, 505 N. Parkway, Memphis, TN 38105.

Give the gift of life.

***Danny Thomas**, Founder*

ST. JUDE CHILDREN'S RESEARCH HOSPITAL

Color-enhanced scanning electron micrograph of *Pneumocystis carinii.*

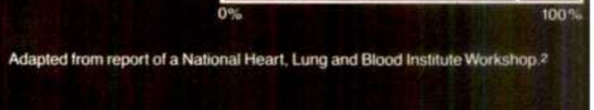
Drug of Choice in *PCP*

Bactrim I.V. is the drug of choice for treatment of *Pneumocystis carinii* pneumonia (*PCP*).[1] Please note, though, that AIDS patients may not tolerate or respond to treatment in the same way as non-AIDS patients.

The incidence of side effects—particularly rash, fever and leukopenia—is greatly increased in AIDS patients. Discontinue therapy at the first sign of skin rash or any adverse reaction.

High survival rate after first episodes of *PCP* in AIDS patients

In a multicenter evaluation of 185 AIDS patients who received trimethoprim plus sulfamethoxazole for their first episodes of *PCP,* 58% completed therapy with this combination alone. Among these patients, the rate of immediate survival was 82%.[2]



Adapted from report of a National Heart, Lung and Blood Institute Workshop.[2]

Bactrim™ I.V. Infusion

(16 mg trimethoprim and 80 mg sulfamethoxazole per mL)

ROCHE®

References: 1. *Medical Letter 28*(706):9-16, Jan 31, 1986. **2.** Murray JF, *et al: N Engl J Med 310*(25):1682-1688, Jun 21, 1984.

Drug of choice in *PCP*.[1]

Bactrim™ I.V. Infusion

(16 mg trimethoprim and 80 mg sulfamethoxazole per mL)

Before prescribing, please consult complete product information, a summary of which follows:

CONTRAINDICATIONS: Hypersensitivity to trimethoprim or sulfonamides; documented megaloblastic anemia due to folate deficiency; pregnancy at term and during the nursing period; infants less than two months of age.

WARNINGS: FATALITIES ASSOCIATED WITH THE ADMINISTRATION OF SULFONAMIDES, ALTHOUGH RARE, HAVE OCCURRED DUE TO SEVERE REACTIONS, INCLUDING STEVENS-JOHNSON SYNDROME, TOXIC EPIDERMAL NECROLYSIS, FULMINANT HEPATIC NECROSIS, AGRANULOCYTOSIS, APLASTIC ANEMIA AND OTHER BLOOD DYSCRASIAS.

BACTRIM SHOULD BE DISCONTINUED AT THE FIRST APPEARANCE OF SKIN RASH OR ANY SIGN OF ADVERSE REACTION. Clinical signs, such as rash, sore throat, fever, arthralgia, cough, shortness of breath, pallor, purpura or jaundice, may be early indications of serious reactions. In rare instances a skin rash may be followed by more severe reactions, such as Stevens-Johnson syndrome, toxic epidermal necrolysis, hepatic necrosis or sefious blood disorder. Perform complete blood counts frequently.

BACTRIM SHOULD NOT BE USED IN THE TREATMENT OF STREPTOCOCCAL PHARYNGITIS. Clinical studies have documented that patients with group A β-hemolytic streptococcal tonsillopharyngitis have a greater incidence of bacteriologic failure when treated with Bactrim than with penicillin.

Bactrim I.V. Infusion contains sodium metabisulfite, which may cause allergic-type reactions in susceptible persons, especially asthmatics or atopic nonasthmatic persons.

PRECAUTIONS:

General: Give with caution to patients with impaired renal or hepatic function, possible folate deficiency (*e.g.*, elderly, chronic alcoholics, patients on anticonvulsants, with malabsorption syndrome, or in malnutrition states) and severe allergies or bronchial asthma. In glucose-6-phosphate dehydrogenase deficient individuals, hemolysis may occur, frequently dose-related.

Local irritation and inflammation due to extravascular infiltration of the infusion have been observed. If these occur, discontinue infusion and restart at another site.

Use in the Elderly: May be increased risk of severe adverse reactions in elderly, particularly with complicating conditions, *e.g.*, impaired kidney and/or liver function, concomitant use of other drugs. Severe skin reactions, generalized bone marrow suppression (see WARNINGS and ADVERSE REACTIONS) or a specific decrease in platelets (with or without purpura) are most frequently reported severe adverse reactions in elderly. In those concurrently receiving certain diuretics, primarily thiazides, increased incidence of thrombocytopenia with purpura reported. Make appropriate dosage adjustments for patients with impaired kidney function (see DOSAGE AND ADMINISTRATION).

Use in the Treatment of Pneumocystis Carinii Pneumonitis in Patients with Acquired Immunodeficiency Syndrome (AIDS): Because of unique immune dysfunction, AIDS patients may not tolerate or respond to Bactrim in same manner as non-AIDS patients. Incidence of side effects, particularly rash, fever, leukopenia, with Bactrim in AIDS patients treated for *Pneumocystis carinii* pneumonitis reported to be greatly increased compared with incidence normally associated with Bactrim in non-AIDS patients.

Laboratory Tests: Perform appropriate culture and susceptibility studies before and throughout treatment. Complete blood counts should be done frequently; if a significant reduction in the count of any formed blood element is noted, discontinue Bactrim. Perform urinalyses with careful microscopic examination and renal function tests during therapy, particularly for patients with impaired renal function.

Drug Interactions: In elderly patients concurrently receiving certain diuretics, primarily thiazides, an increased incidence of thrombocytopenia with purpura has been reported. Bactrim may prolong the prothrombin time in patients who are receiving the anticoagulant warfarin. Keep this in mind when Bactrim is given to patients already on anticoagulant therapy and reassess coagulation time. Bactrim may inhibit the hepatic metabolism of phenytoin. Given at a common clinical dosage, it increased the phenytoin half-life by 39% and decreased the phenytoin metabolic clearance rate by 27%. When giving these drugs concurrently, be alert for possible excessive phenytoin effect. Sulfonamides can displace methotrexate from plasma protein binding sites, thus increasing free methotrexate concentrations.

Drug/Laboratory Test Interactions: Bactrim, specifically the trimethoprim component, can interfere with a serum methotrexate assay as determined by the competitive binding protein technique (CBPA) when a bacterial dihydrofolate reductase is used as the binding protein. No interference occurs if methotrexate is measured by a radioimmunoassay (RIA). The presence of trimethoprim and sulfamethoxazole may also interfere with the Jaffé alkaline picrate reaction assay for creatinine, resulting in overestimations of about 10% in the range of normal values.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenesis: Long-term studies in animals to evaluate carcinogenic potential not conducted with Bactrim I.V. Infusion. *Mutagenesis:* Bacterial mutagenic studies not performed with sulfamethoxazole and trimethoprim in combination. Trimethoprim demonstrated to be nonmutagenic in the Ames assay. No chromosomal damage observed in human leukocytes cultured *in vitro* with sulfamethoxazole and trimethoprim alone or in combination; concentrations used exceeded blood levels of these compounds following therapy with Bactrim. Observations of leukocytes obtained from patients treated with Bactrim revealed no chromosomal abnormalities. *Impairment of Fertility:* Bactrim I.V. Infusion not studied in animals for evidence of impairment of fertility. Studies in rats at oral dosages as high as 70 mg/kg trimethoprim plus 350 mg/kg sulfamethoxazole daily showed no adverse effects on fertility or general reproductive performance.

BACTRIM™ I.V. Infusion (trimethoprim and sulfamethoxazole/Roche)

Pregnancy: Teratogenic Effects: Pregnancy Category C. Trimethoprim and sulfamethoxazole may interfere with folic acid metabolism; use during pregnancy only if potential benefit justifies potential risk to fetus. Nonteratogenic Effects: See CONTRAINDICATIONS section.

Nursing Mothers: See CONTRAINDICATIONS section.

Pediatric Use: Not recommended for infants under two months (see CONTRAINDICATIONS section).

ADVERSE REACTIONS: Most common are gastrointestinal disturbances (nausea, vomiting, anorexia) and allergic skin reactions (such as rash and urticaria). **FATALITIES ASSOCIATED WITH THE ADMINISTRATION OF SULFONAMIDES, ALTHOUGH RARE, HAVE OCCURRED DUE TO SEVERE REACTIONS, INCLUDING STEVENS-JOHNSON SYNDROME, TOXIC EPIDERMAL NECROLYSIS, FULMINANT HEPATIC NECROSIS, AGRANULOCYTOSIS, APLASTIC ANEMIA AND OTHER BLOOD DYSCRASIAS (SEE WARNINGS SECTION).** Local reaction, pain and slight irritation on I.V. administration infrequent. Thrombophlebitis rarely observed.

Hematologic: Agranulocytosis, aplastic anemia, thrombocytopenia, leukopenia, neutropenia, hemolytic anemia, megaloblastic anemia, hypoprothrombinemia, methemoglobinemia, eosinophilia. *Allergic Reactions:* Stevens-Johnson syndrome, toxic epidermal necrolysis, anaphylaxis, allergic myocarditis, erythema multiforme, exfoliative dermatitis, angioedema, drug fever, chills, Henoch-Schoenlein purpura, serum sickness-like syndrome, generalized allergic reactions, generalized skin eruptions, conjunctival and scleral injection, photosensitivity, pruritus, urticaria and rash. Periarteritis nodosa and systemic lupus erythematosus have been reported. *Gastrointestinal:* Hepatitis (including cholestatic jaundice and hepatic necrosis), elevation of serum transaminase and bilirubin, pseudomembranous enterocolitis, pancreatitis, stomatitis, glossitis, nausea, emesis, abdominal pain, diarrhea, anorexia. *Genitourinary:* Renal failure, interstitial nephritis, BUN and serum creatinine elevation, toxic nephrosis with oliguria and anuria, crystalluria. *Neurologic:* Aseptic meningitis, convulsions, peripheral neuritis, ataxia, vertigo, tinnitus, headache. *Psychiatric:* Hallucinations, depression, apathy, nervousness. *Endocrine:* Sulfonamides bear certain chemical similarities to some goitrogens, diuretics (acetazolamide and the thiazides) and oral hypoglycemic agents; cross-sensitivity may exist. Diuresis and hypoglycemia have occurred rarely in patients receiving sulfonamides. *Musculoskeletal:* Arthralgia, myalgia. *Respiratory:* Pulmonary infiltrates. *Miscellaneous:* Weakness, fatigue, insomnia.

DOSAGE AND ADMINISTRATION: CONTRAINDICATED IN INFANTS LESS THAN TWO MONTHS OF AGE. CAUTION—BACTRIM I.V. INFUSION MUST BE DILUTED IN 5% DEXTROSE IN WATER SOLUTION PRIOR TO ADMINISTRATION. DO NOT MIX WITH OTHER DRUGS OR SOLUTIONS. RAPID INFUSION OR BOLUS INJECTION MUST BE AVOIDED.

DOSAGE *(Children and Adults):*

PNEUMOCYSTIS CARINII PNEUMONITIS: Total daily dose is 15 to 20 mg/kg (based on the trimethoprim component) given in three or four equally divided doses every 6 to 8 hours for up to 14 days. One investigator noted that a total daily dose of 10 to 15 mg/kg was sufficient in 10 adults with normal renal function.

SEVERE URINARY TRACT INFECTIONS AND SHIGELLOSIS: Total daily dose is 8 to 10 mg/kg (based on the trimethoprim component) given in two to four equally divided doses every 6, 8 or 12 hours for up to 14 days for severe urinary tract infections and 5 days for shigellosis. Maximum recommended daily dose is 60 ml. *Renal Impaired:* Creatinine clearance above 30 ml/min, give usual dosage; 15-30 ml/min, give one-half the usual regimen; below 15 ml/min, use not recommended.

Method of Preparation: Bactrim I.V. Infusion must be diluted. EACH 5 ML SHOULD BE ADDED TO 125 ML OF 5% DEXTROSE IN WATER. After diluting do not refrigerate; use within 6 hours. If a dilution of 5 ml/100 ml of 5% dextrose in water is desired, use within 4 hours. If there is cloudiness or evidence of crystallization, discard solution and prepare a fresh one.

Multidose Vials: After initial entry into the vial, use remaining contents within 48 hours. The following infusion systems are satisfactory: unit-dose glass containers; unit-dose polyvinyl chloride and polyolefin containers.

Dilution: ADD EACH 5 ML OF BACTRIM I.V. INFUSION TO 125 ML OF 5% DEXTROSE IN WATER.

NOTE: *When fluid restriction is desirable*, add each 5 ml to 75 ml of 5% dextrose in water; mix just prior to use and administer within two hours. If there is cloudiness or evidence of crystallization, discard solution and prepare a fresh one.

DO NOT MIX BACTRIM I.V. INFUSION—5% DEXTROSE IN WATER WITH DRUGS OR SOLUTIONS IN THE SAME CONTAINER.

ADMINISTRATION: Administer by I.V. infusion over 60 to 90 minutes. Avoid rapid infusion or bolus injection. Do not give intramuscularly.

HOW SUPPLIED: 5-ml ampuls, 5-ml vials and 10-ml vials—boxes of 10; 30-ml and 50-ml multidose vials—boxes of 1. Each 5 ml contains 80 mg trimethoprim (16 mg/ml) and 400 mg sulfamethoxazole (80 mg/ml) for infusion with 5% dextrose in water.

STORE AT ROOM TEMPERATURE (15°-30°C or 59°-86°F). DO NOT REFRIGERATE.

PUZZLED ABOUT THOSE
EXTRA REACTIONS? — The Answer . . . MONOCLONALS

New from Pel-Freez for Clinical and Basic Research, we have a large collection of Monoclonals (in excess of 200).

HUMAN LEUKOCYTES
B cells, T cells, (also activation markers), Natural killer cells, Monocytes, Granulocytes, Platelets (Gp Ib, Gp IIb-IIIA)

IMMUNOGLOBULINS
IgA, IgD, IgE, IgG subclasses, IgM, Lambda and Kappa chains

HLA MOLECULES
Class I, Class II, B_2-Microglobulin

COAGULATION FACTORS
Factor VIII, Fibrinogen, Fibronectin, Thrombospondin, Tissue Plasminogen Activator

BLOOD GROUPS

DIFFERENTIATION MARKERS ON HUMAN TISSUE
Keratin, Desmin, Villin, Vimentin, Neurofilament

PITUITARY HORMONES
HCG, FSH, LH, TSH, Prolactin, Thyroglobulin, Leukemia cell markers

TUMOR MARKERS
Alpha Foeto Protein, Carcinoembryonic Antigen

VIRAL ANTIGENS

STEROIDS AND OTHER HAPTENS

AND MORE . . . .

These monoclonals can be supplied as ascites fluid, or in fluoresceinated, biotinated or unconjugated forms. Second step reagents are available for ELISA assays, immunocytochemistry and immunofluorescence.

For research use only

Hemophilia.
Home Hemophilia Services.
Caremark/Western Medical Specialties.

Just part of the picture.

Advances in the field of hemophilia research over the past twenty years have yielded sophisticated, yet uncomplicated treatment methods that allow persons with hemophilia to focus on a brighter future. Where once was a corridor of closed doors, now appears a wealth of new physical, mental and occupational growth possibilities. In concert with the care program designed for your patients with hemophilia, Western Medical Specialties can provide convenient, reliable delivery of all major brands of anti-hemophilic factor and ancillary supplies to your office, the patient's home or place of business. WMS third party insurers directly (inclu both state and federal programs) provides follow-up documentatio each shipment. Western Medical Specialties: Just part of the total-picture for your patients with hemophilia.

NOT ALL ANTI-LEUKOCYTE REAGENTS ARE ALIKE.

Only Olympus, your colleague in immunology, offers monoclonal antibodies of the specificity *and* the quality your research applications demand.

Olympus anti-human leukocyte MAb's assure you of reliable and reproducible results. Our broad selection includes products specific for T and B lymphocyte subsets, the T cell antigen receptor, leukemia and lymphoma cells, HLA and related markers, and the interleukin 2 receptor. Developed and manufactured by United Biomedical, Inc., all products have been thoroughly characterized and exhaustively field-tested. They're available in purified form, conjugated to FITC or biotin, or in culture supernatants and are supported by a complete range of second-step reagents.

Add to that *the most complete selection anywhere* of MAb's specific for human cytokines.

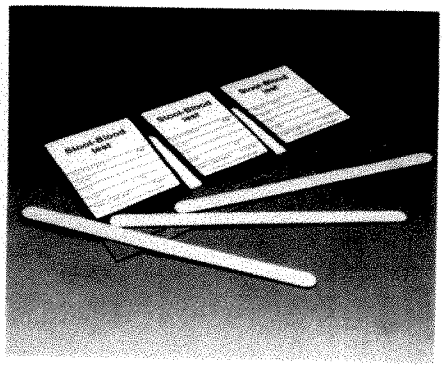
50,000 people will be saved from colorectal cancer this year. You can save one.



Save yourself! Colorectal cancer is the second leading cause of cancer deaths after lung cancer. More than 90% of colorectal cancers occur equally in men and women past age 50. Early detection provides the best hope of cure. That's why if you're over 50, you should take this simple, easy Stool Blood Test every year. The test kit is chemically treated to detect hidden blood in the stool and can be done at the time of your periodic health examination so your doctor will know the results.

Two days before the test, you begin a diet you might enjoy all the time. Plenty of fresh vegetables raw or cooked, especially corn, spinach and lettuce. Lots of plums, grapes, apples and prunes, moderate amounts of peanuts and popcorn. No red meat, turnips or horseradish. Do's and don't's are listed in the kit.

The presence of hidden blood usually indicates some problem in the stomach or bowel, not necessarily cancer. Positive tests must be followed by further testing to find out what the problem is.

Other tests for colorectal cancer you should talk to your doctor about: Digital rectal exam (after age 40); the procto test (after age 50). It is important to report any personal or family history of intestinal polyps or ulcerative colitis, and any change in your bowel habits, which could be a cancer warning signal.

The American Cancer Society wants you to know.

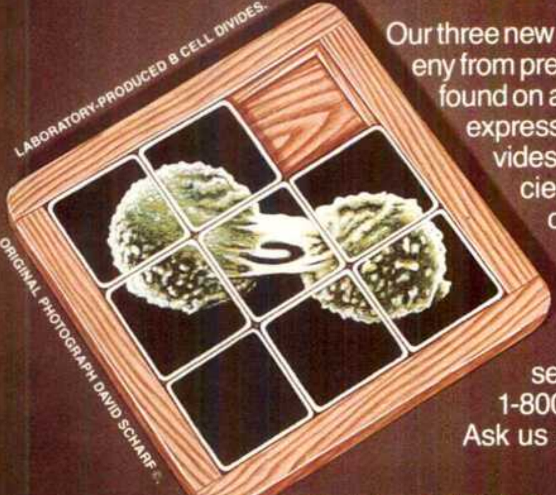
B CELL ACTIVATION GOT YOU PUZZLED?

COULTER HAS THE SOLUTION.



LABORATORY-PRODUCED B CELL DIVIDES.

ORIGINAL PHOTOGRAPH DAVID SCHARF ©

Our three new B cell markers make it possible to study B cell ontogeny from pre-B stem cells to plasma cells. B5 and B6 (CD23) are found on activated B cells, and not on resting B cells. The wide expression of the B5 antigen on B cell malignancies provides evidence for the hypothesis that all B cell malignancies are derived from subpopulations of activated B cells. B3 (CD22) is clearly unique: B3 is expressed on some pre-B cells, approximately 75% of resting B cells, and is lost with activation. Expand your research on AIDS, autoimmune diseases, and lymphoproliferative disorders with this complete series of B cell monoclonals. For more information, call 1-800-327-3778 (in Florida, 1-800-432-6518, Ext. 6880). Ask us about our complete line of monoclonal antibodies and support products.

Blenoxane® *(sterile bleomycin sulfate)*

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane* be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents.

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and vulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of the lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{co}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{co} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{co} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

(1) Maintain $FI\ O_2$ at concentrations approximately that of room air (25%) during surgery and the postoperative period.

(2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban*. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane, as sterile bleomycin sulfate. NDC 0015-3010-20

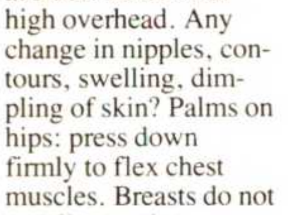
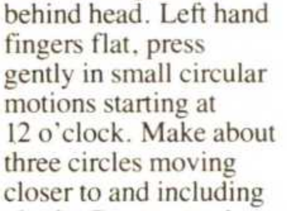
Read this like your life depends on it.

Breast cancer found early and treated promptly has an excellent chance for cure. About a week after your period, when breasts are normal, practise this self-exam. Ask your doctor to teach you this method:

1. In bath or shower.
Fingers flat, move opposite hand gently over each breast. Check for lumps, hard knots, thickening.



2. In front of a mirror.
Observe breasts. Arms at sides. Raise arms high overhead. Any change in nipples, contours, swelling, dimpling of skin? Palms on hips: press down firmly to flex chest muscles. Breasts do not usually match.



3. Lying down.
Pillow under right shoulder, right hand behind head. Left hand fingers flat, press gently in small circular motions starting at 12 o'clock. Make about three circles moving closer to and including nipple. Reverse and repeat on left.

REVIEW ARTICLE

The HL-60 Promyelocytic Leukemia Cell Line: Proliferation, Differentiation, and Cellular Oncogene Expression

By Steven J. Collins

The HL-60 cell line, derived from a single patient with acute promyelocytic leukemia, provides a unique in vitro model system for studying the cellular and molecular events involved in the proliferation and differentiation of normal and leukemic cells of the granulocyte/monocyte/macrophage lineage.

© 1987 by Grune & Stratton, Inc.

ALTHOUGH LEUKEMIC cells from patients with acute myeloid leukemia display a seemingly unlimited proliferative capacity in vivo, their life span in liquid suspension culture is usually limited to a few cell divisions. One possible explanation for such limited in vitro proliferation is that certain growth factors sustaining leukemic cell division in the patient are absent from the in vitro culture environment. About 10 years ago, investigators in Dr R. C. Gallo's laboratory at the National Institutes of Health (NIH), in an attempt to identify such leukemia-specific growth factors, cultured fresh human leukemic cells with conditioned media derived from cultures of both human embryonic cells and mitogen-stimulated lymphocytes.[1] Although the postulated leukemia-specific growth factor was never reproducibly identified, this experimental approach proved fruitful in a number of unexpected ways. The T cell mitogen interleukin 2 (TCGF) was first identified,[2] and a factor-independent immortal cell line (HL-60) with distinct myeloid characteristics was developed.[3,4] The HL-60 cell line, derived from a patient with acute promyelocytic leukemia, can be induced to differentiate in vitro to a number of different cell types, and studies with this leukemic cell line have proved invaluable in a variety of different areas. These include: (a) providing insight into the control mechanisms of normal granulocyte/monocyte/macrophage differentiation; (b) suggesting new therapeutic approaches for patients with leukemia; (c) providing a ready source of cDNA for cloning of important granulocyte and monocyte enzymes and monokines; (d) providing insight into possible mechanisms of rapid regulation of gene transcription; and (e) serving as an invaluable model for studying specific cellular oncogene expression in relationship to particular hematopoietic differentiative lineages. This review attempts to summarize the important characteristics of this unique cell line, with particular emphasis on HL-60 proliferation, differentiation, and cellular oncogene expression.

GROWTH AND PROLIFERATION

HL-60 promyelocytic leukemia cells continuously proliferate in suspension culture with a doubling time of ~36 to 48 hours. This characteristic alone makes HL-60 unusual among human myeloid leukemias. Most fresh myeloid leukemia cells when cultured in liquid suspension undergo a limited number of cell divisions prior to growth arrest and cell death, and relatively few human leukemic cell lines displaying distinct myeloid or myelomonocytic characteristics have been established. What are the characteristics of HL-60 cells that make them adapted to such continuous growth in liquid suspension? HL-60 cell surface expression of transferrin and insulin receptors appears critical to their proliferative capacity. HL-60 cells can proliferate in serum-free nutrient media (eg, RPMI 1640) provided that it is supplemented with transferrin and insulin.[5] The requirement for insulin and transferrin is absolute, as HL-60 proliferation immediately ceases if either of these compounds is removed from the serum-free culture media.[5] Transferrin requirement by HL-60 as well as by other cultured cells[6] indicates that an active iron transport system is necessary for cell proliferation. HL-60 cells express the transferrin receptor on the cell surface, and this receptor expression markedly decreases as the cells are induced to differentiate terminally.[7,8] Moreover, monoclonal antibodies to the transferrin receptor inhibit HL-60 cell proliferation.[9] Similarly, insulin receptors are also displayed by HL-60 cells, and insulin receptor expression decreases with granulocytic differentiation of HL-60.[10] The presence of the insulin and transferrin receptors on HL-60 cells cannot, however, in itself explain the unusual in vitro proliferative capacity of this cell line since a number of fresh leukemia cells also display these

receptors but nevertheless are unable to grow continuously in culture.

The in vitro proliferation of normal myeloid progenitor cells is stimulated by the colony-stimulating factor (CSF) family of compounds. Certain CSFs also stimulate the proliferation of HL-60 cells.[11-13] HL-60 cells have been postulated to produce certain CSF-like compounds that act as autostimulators of HL-60 growth, and several compounds exhibiting such "autocrine" activity have been partially purified from HL-60–conditioned media. Brennan et al described a 13,000 mol wt compound produced by HL-60 cells which stimulated HL-60 cell growth but which exhibited no CSF activity on normal mouse bone marrow cells.[14] Perkins et al described a 25,000 mol wt HL-60 product with similar HL-60 autostimulatory activity. In addition, this compound exhibits CSF activity on normal bone marrow and shares antigenic determinants with certain CSFs.[15] These HL-60 autostimulatory products have not been molecularly cloned, and it is presently unclear what their exact relationship is to each other or to the normal CSF molecules. One of the chromosome 5 GM-CSF alleles appears to be partially deleted in HL-60 cells,[16] but there is no evidence that this gene is expressed in HL-60 cells, and the effect, if any, of this genomic rearrangement on the proliferation of HL-60 is presently unknown.

HL-60 cells also exhibit genetic abnormalities in specific cellular oncogenes (see below), and these abnormalities most likely also play a role in the unusual ability of these myeloid leukemic cells to proliferate continuously in vitro.

DIFFERENTIATION

The characteristic of HL-60 cells that has attracted the most research interest is their capacity to differentiate in vitro to a variety of different cell types of the myelomonocytic lineage. Various agents induce HL-60 cells to differentiate to four general types of cells: (a) granulocytes, (b) monocytes, (c) macrophagelike cells, and (d) eosinophils. These designations are somewhat arbitrary, and certain HL-60–inducing agents give rise to cells with characteristics that overlap these categories. Moreover, as emphasized later, the induced HL-60 cells are usually deficient in certain characteristics of their normal cell counterpart. Nevertheless, these categories provide a convenient outline for discussing the numerous and complex phenotypic changes induced in this leukemic cell line by a wide variety of agents. These categories are discussed separately below.

Granulocytes. The HL-60 cells are predominantly promyelocytes but in most cell cultures, particularly passage 60 or less, ~5% of the cells exhibit spontaneous differentiation to morphologically mature cells including myelocytes, metamyelocytes, banded and segmented neutrophils.[3] The addition to these cultures of specific inducing agents, including polar-planer compounds such as dimethyl sulfoxide DMSO,[17] or other agents such as retinoic acid[18] markedly increases this spontaneous differentiation, with most cells acquiring morphological, functional, enzymatic, and surface membrane antigen characteristics of mature granulocytes (Table 1). A variety of different compounds induces such granulocytic differentiation of HL-60 cells (Table 2). Many of these compounds also induce erythroid differentiation in Friend mouse erythroleukemia cells.[19,20] By several criteria, this granulocytic differentiation of HL-60 cells is somewhat incomplete and defective. For example, most granulocyte-induced cultures consist predominantly of metamyelocytes and banded neutrophils rather than fully differentiated multilobulated polys. In addition, the granulocyte-induced HL-60 cells lack lactoferrin, suggesting that they are deficient in secondary granules.[21,22] The LDH isoenzyme profile of granulocyte-induced HL-60 differs quantitatively from the LDH isoenzymes of normal granulocytes consistent with incomplete differentiation.[23] Deficiencies have been described in the myeloperoxidase/peroxide/halide killing sys-

Table 1. Phenotypic Characteristics of Induced HL-60 Cells

Characteristic	Uninduced	Granulocyte	Monocyte	Macrophagelike	Eosinophil
Myeloperoxidase	+[3,4]	↓[22,147]	↓[22,42]	↓[61]	+[96,97]

Arrows indicate a quantitative increase (↑) or decrease (↓) from uninduced HL-60 levels. Blank spaces correspond to characteristics absent from the literature, (+) indicates present, (−) indicates absent, ± indicates discrepant or equivocal literature findings.

Table 2. Inducers of Differentiation of HL-60 Cells

	Induced Cell Type			
	Granulocyte	Monocyte	Macrophagelike	Eosinophil
Inducing agents	Polar-planer compounds[17]	Vitamin D_3[47-50]	Phorbol esters (TPA)[61,62]	Alkaline media[97]
	Retinoic acid[18]	Na Butyrate[155]	Teleocidin[161,162]	Butyric acid[98]
	Actinomycin D[20]	Lymphocyte-conditioned media[51]		GM-CSF[5]
	Hypoxanthine[20]	DIF[53]		
	Antithymocyte globulin[156]	IFN-γ[45,54-56]		
	Tunicamycin[157]	Tumor necrosis factor[59]		
	6-thioguanine[20]	Ara C[159]		
	L-ethionine[158]	Ara A[160]		

tem in HL-60 granulocytes.[24] Unlike other granulocyte inducers, retinoic acid treated HL-60 granulocytes do not display an increase in chemotactic peptide receptors.[25]

Despite these deficiencies, most of the granulocyte-inducing agents induce terminal differentiation of HL-60 cells; that is, the induced cells are no longer capable of proliferation. This together with the functional maturation of these cells, which enables them to engage in the killing of microorganisms (Table 1), suggests that these granulocyte inducers, particularly retinoic acid, may be of therapeutic benefit in patients with myelogenous leukemia. Unfortunately, HL-60 cells appear to be quite exceptional among acute nonlymphocytic leukemias (ANL) in their response to granulocyte differentiation inducers. Indeed, most fresh leukemic cells in short-term culture in the presence of granulocyte-inducing agents do not exhibit differentiation.[26,27] Nevertheless, a subset of ANL patients exists, primarily those classified as acute promyelocytic leukemia, whose leukemic cells clearly exhibit induced granulocytic differentiation in vitro.[26] Moreover, there are several anecdotal reports of patients with promyelocytic leukemia and with myelodysplastic syndrome who have apparently benefited from systemic therapy with retinoic acid.[28-32]

The mechanism of action of the HL-60 granulocyte inducers is unknown. At least a 12-hour exposure to DMSO or retinoic acid is necessary before any differentiation occurs and continuous exposure to these compounds generally is required to induce maximum differentiation.[18,33] Although retinoic acid is believed to exert its biologic effect in many cells by interacting with a specific cytoplasmic retinoic-acid binding protein (RABP),[34,35] our own observations and those of other researchers[36] indicate that HL-60 cells lack such a binding protein. Evidence that retinoic acid-induced HL-60 differentiation is initiated at the cell surface is provided by the observation that granulocytic differentiation occurs in HL-60 cells when cultured with retinoic acid immobilized on a solid substrate.[37] HL-60 cell lines resistant to the differentiation-inducing effects of retinoic acid exhibit an apparent high-mol-wt acidic surface membrane glycoprotein that is absent from the wild-type HL-60 cells.[38,39] This aberrant surface membrane glycoprotein is hyposialyated, but its relationship to the retinoic acid resistance is presently uncertain.[40]

Monocytes. Different compounds induce HL-60 to differentiate to cells exhibiting distinct "monocytic" characteristics. These cells morphologically can be confused with immature HL-60 granulocytes, and they share many important functional characteristics with HL-60 cells treated with granulocytic inducers (Table 1). They can be readily distinguished from these latter cells, however by different markers, including positive staining for the monocyte/macrophage specific enzyme α-napthyl acetate esterase (nonspecific esterase-NSE),[41] by the presence of monocyte specific cell membrane antigens,[42-44] and by their capacity for mediating antibody-dependent cytoxicity (ADCC).[44-46]

A variety of different naturally occurring compounds induces monocytic differentiation of HL-60. These include vitamin D_3 as well as various products found in mitogen-stimulated lymphocyte-conditioned media (LCM).[47-51] 1,25 dihydroxyvitamin D_3 induces monocytic differentiation of HL-60 cells at concentrations as low as 10^{-10} mol/L[47-50] and specific high-affinity cytosol receptors for vitamin D_3 have been observed in HL-60.[48] This compound also induced monocyte/macrophage differentiation in normal human bone marrow cells.[49] Vitamin D_3 could have therapeutic potential but, as with retinoic acid, HL-60 cells appear to be unusual among ANL cells in their differentiative response to this agent. Other naturally occurring compounds of interest that induce monocytic differentiation of HL-60 cells include various products produced by mitogen-stimulated mononuclear cell cultures.[51] An HL-60 monocyte-inducing compound with mol wt of ~40,000 termed differentiation-inducing factor (DIF) has been isolated from LCM and from CM from the T cell leukemia cell line HUT-102.[52,53] Another mitogen-stimulated lymphocyte product, γ-interferon, (IFN-γ) induces monocytic differentiation of HL-60,[45,54-56] whereas IFN-α and IFN-β alone do not exhibit this inducing capacity. Synergism among different naturally occurring compounds has been demonstrated in the induction of monocytic differentiation of HL-60. For example, retinoic acid in relatively small concentrations synergistically acts with DIF,[57] IFN-γ[46] and IFN-α[46,58] to induce monocytic differentiation of HL-60. This latter finding is interesting since retinoic acid by itself is a granulocytic inducer of HL-60. In addition, lymphotoxin and tumor necrosis factor (cachectin), which are also products of mitogen-stimulated mononuclear cells, also act in synergy to promote IFN-γ–induced differentiation of HL-60.[59]

Therapeutically, monocytic differentiation of HL-60, unlike granulocytic differentiation, is not necessarily accompanied by the loss of proliferative capacity of the induced cells (ie, monocytic HL-60 differentiation is not necessarily terminal differentiation). For example, recombinant IFN-γ alone as well as IFN-γ plus retinoic acid induces monocytic characteristics of HL-60 cells, but they have little effect on inhibiting HL-60 cell proliferation.[45,46] Moreover, Elias et al identified a factor in mitogen-stimulated LCM that markedly enhances thymidine incorporation of HL-60 cells.[60] An early stimulatory effect of tumor necrosis factor on HL-60 thymidine incorporation has also been observed.[59] Thus, monocytic differentiation of HL-60 may in certain cases be preceded by enhanced cell proliferation, and HL-60 cells induced to acquire particular monocytic characteristics have not necessarily lost the capacity to proliferate.

Macrophagelike. The primary inducer of macrophagelike HL-60 cells is the phorbol ester tumor promoter 12-O-tetradecanoylphorbol-13-acetate (TPA). This TPA-induced macrophagelike phenotype is frequently combined with the "monocytic" phenotype in discussions of HL-60 differentiation; indeed, these induced cell types both share many of the same enzymatic, histochemical, and functional characteristics (Table 1). Several important phenotypic characteristics clearly distinguish the HL-60 macrophagelike differentiation from HL-60 monocytic differentiation, however. First, TPA-treated HL-60 cells are markedly more adherent than HL-60 monocytes. TPA-treated cells exhibit intense adherence to plastic with prominent pseudopodia formation and also markedly adhere to each other.[61,62] Second, several specific surface antigens present on normal and HL-60 monocytes are not induced in TPA-treated HL-60 cells.[42,43,50,65] Third, no induction of chemotactic peptide receptors or of NBT reduction activity occurs in TPA-treated HL-60,[25,66] whereas these characteristics are readily demonstrated in HL-60 monocytes.[52,56] In contrast to monocytic induction, TPA induction of HL-60 is associated with a rapid profound loss in proliferative capacity. Few HL-60 cells are able to enter S-phase after exposure to TPA.[61,62] Moreover, TPA-induced HL-60 differentiation can occur in the absence of cell division or new DNA synthesis.[63,64] Fifth, in contrast to the HL-60 granulocyte and monocyte inducers, prolonged exposure to TPA is not necessary to induce macrophagelike differentiation. Significant macrophagelike differentiation occurs in HL-60 cells after TPA exposure as short as 20 minutes.[61] Finally, unlike the granulocytic and monocytic HL-60 inducers, TPA induction is not confined to a small subset of fresh nonlymphocytic leukemia cells. Indeed, most acute myeloid leukemia cells as well as chronic myelogenous leukemia (CML) blast crisis cells exhibit this macrophagelike differentiation when exposed to TPA.[67-69]

There is a curious dose dependency of the TPA-induced phenotypic changes in HL-60 cells. At low doses of TPA (3×10^{-10} mol/L), HL-60 colony formation in soft agar in the absence of colony-stimulating factor (CSF) is enhanced ~ twofold (S. Collins, unpublished observations). Such colony formation is suppressed at TPA concentrations of $\geq 10^{-9}$ mol/L. This dose-dependent TPA stimulation is similar to that reported on the KG-1 myeloid leukemia cell line[70] as well as on fresh human myeloid leukemic cells[71] and on mouse bone marrow colony-forming cells.[72] At slightly higher concentrations (4×10^{-10} mol/L), TPA has induced granulocytic differentiation of HL-60 in liquid suspension culture.[73] Concentrations $>5 \times 10^{-10}$ mol/L induced the macrophagelike phenotype. Thus, at low concentrations of TPA, HL-60 proliferation is somewhat enhanced, at slightly higher concentrations granulocytic maturation occurs and, at still higher concentrations, the macrophagelike HL-60 phenotype is induced.

TPA exerts different phenotypic changes on HL-60 cells depending on the differentiative state of these cells. In HL-60 cells induced to granulocytes or monocytes TPA induces respiratory burst activity with the conversion of oxygen to superoxide anion.[52,74] This reaction forms the basis for the nitroblue tetrazolium (NBT) test, which is commonly used to quantitate HL-60 differentiation since undifferentiated HL-60 cells do not exhibit this particular response to TPA.[74,75] Similarly, TPA rapidly induces chemiluminescence in HL-60 cells induced to granulocytes but not in uninduced HL-60.[76]

In contrast to the granulocytic and monocytic HL-60 inducers considerable information is available related to the mechanism of action of TPA. HL-60 variant subclones have been isolated that are resistant to DMSO but that differentiate with TPA, suggesting that different pathways are involved in DMSO- and TPA-induced HL-60 differentiation.[77] TPA may exert many of its effects through protein kinase C, a calcium- and phospholipid-dependent enzyme that is widely distributed in numerous tissues and which plays a crucial role in transducing various extracellular signals across the cell membrane.[78,79] HL-60 cells harbor specific receptors for TPA,[80,81] and considerable evidence in HL-60 as well as in other cells shows that the TPA receptor is indeed protein kinase C.[82-84] Normally, protein kinase C is transiently activated by diacylglycerol, but TPA can substitute for endogenous diacylglycerol, resulting in prolonged activation of the enzyme.[85] This activation of protein kinase C in HL-60 cells could result in the phosphorylation of specific substrate proteins leading to the macrophagelike phenotypic changes induced by TPA. What are the possible substrates for activated protein kinase C in TPA-stimulated HL-60 cells? Following 1-hour treatment with TPA, increased phosphorylation of at least 14 proteins has been noted in HL-60.[86] Specifically, rapid phosphorylation of the HL-60 transferrin receptor occurs, associated with a decline in surface transferrin-receptor number.[87] In addition, phosphorylation of two cytosol proteins (17 and 27 kd in size) occurs in HL-60 cells within 15 minutes after exposure to TPA.[88] Activation of topoisomerase II by protein kinase C has been observed in vitro and this, together with the observation that TPA-induced HL-60 differentiation is partially blocked by inhibitors of topoisomerase II, suggests that this DNA-modulating enzyme could be an important target for activated protein kinase C in TPA-treated HL-60 cells.[89]

HL-60 variants stably resistant to TPA-induced differentiation have been derived by culturing the cells in gradually increasing concentrations of TPA.[90,91] These TPA-resistant HL-60 cells generally exhibit the same number of TPA receptors exhibited by wild-type HL-60.[90,91] Moreover, similar cellular proteins are rapidly phosphorylated after TPA exposure in both the TPA-sensitive and TPA-resistant HL-60 cells, but the quantitative level of this rapid phosphorylation is significantly less in the TPA-resistant *v* the TPA-sensitive cells.[92] These observations suggest that a block exists in the enzymatic activity of protein kinase C after its interaction with TPA in the TPA-resistant cells. This block may be related to the aberrant translocation of this enzyme from cytosol to membrane fractions that has been observed in the TPA-resistant HL-60 cells as compared with the TPA-sensitive HL-60 cells.[93]

The TPA-induced binding to, and activation of, protein kinase C appears to be important in the TPA-induced differentiation of HL-60 cells. Several observations suggest, however, that activation of protein kinase C cannot by itself account for this macrophagelike differentiation. For example, the synthetic diacylglycerol l-oleoyo-2-acetylglycerol (OAG) binds to and activates protein kinase C and induces the rapid phosphorylation of HL-60 cellular proteins.[86] This compound, however, does not induce HL-60 differentiation.[86] Similarly, the macrocyclic lactone bryostatin binds to and activates protein kinase C in HL-60 but actually inhibits TPA-induced HL-60 differentiation in a dose-dependent manner.[94] These observations suggest that a TPA effect other than, or in addition to, activation of protein kinase C must account for the macrophagelike differentiation of HL-60. The nature of this additional TPA action remains to be defined.

Eosinophils. Several observers have noted cells positive for the eosinophil specific Luxol-fast-blue stain in a small percentage (4% to 7%) of HL-60 colonies cloned in semisolid agar culture.[12,95] The proportion of colonies containing such cells increased with the addition of crude preparations of GM-CSF. Preparations containing EO-CSF, which stimulates the formation of normal eosinophil colonies, had no effect on the incidence of such colonies.[12] Similarly, purified recombinant GM-CSF induces a small but significant increase in the number of Biebrich scarlet cells in HL-60 liquid suspension cultures.[13] Moreover, variant HL-60 subclones exhibiting virtually 100% staining with Biebrich scarlet as well as other eosinophil characteristics have been isolated and stably maintained in continuous suspension culture.[96] Fischkoff et al noted that the proportion of cells exhibiting eosinophilic characteristics in the wild type HL-60 line could be markedly increased by culturing the cells in slightly alkaline media (pH 7.6 to 7.8).[97] These induced cells have been extensively characterized and demonstrate multiple eosinophilic granule proteins, including the eosinophil major basic protein (MBP), the Charcot-Leyden Crystal (CLC) protein, eosinophil peroxidase, acid phosphatase, and arylsulfatase.[97,98] Parental, uninduced HL-60 cells also exhibit the eosinophil MBP. The amount of this protein markedly diminishes when the culture is treated with granulocytic inducers such as DMSO.[97]

Some of the HL-60 eosinophilic characteristics are aberrant as compared with those of normal eosinophils. This is particularly true with regard to granule formation. For instance, the HL-60 eosinophilic granules are chloroacetate esterase and PAS positive, whereas normal eosinophilic granules are negative for both.[97] HL-60 eosinophils express significantly less CLC and arylsulfatase protein than do normal eosinophils.[98] Such abnormalities are similar to those observed in the dysplastic eosinophils present in the bone marrow of patients with acute myelomonocytic leukemia. This latter syndrome is associated with karyotypic abnormalities involving the long arm of chromosome 16,[99,100] and similar karyotypic abnormalities in this chromosome region have been noted in HL-60 metaphases.[97]

HL-60 ONCOGENE STRUCTURE AND EXPRESSION

HL-60 cells provide an invaluable model system for studying the relationship of oncogene structure and expression to normal and leukemic cell proliferation and differentiation. Several mutations involving specific cellular oncogenes have been noted in HL-60, reinforcing the concept that the development of malignancy is a multistage phenomenon, that cancer results not from a single mutation but from a series of mutations. In addition, studies on HL-60 have provided important insight into the relationship of specific oncogene expression to differentiation along a specific hematopoietic lineage.

HL-60 cells exhibit specific genomic mutations involving the cellular oncogenes c-*myc*, N-*ras* and p53. These are discussed separately.

*c-*myc *amplification.* The human c-*myc* gene is defined by virtue of its homology to v-*myc*, the transforming gene of the avian myelocytoma virus, which induces myeloid tumors in chicks. The protein product of this cellular oncogene is localized in the nucleus,[101] and enhanced expression of the c-*myc* gene is rapidly induced following mitogenic stimulation of resting lymphocytes or fibroblasts.[102] In addition, this oncogene acts in concert with other oncogenes, particularly those in the *ras* gene family, to malignantly transform primary rodent fibroblast cultures.[103] HL-60 cells exhibit a 15- to 30-fold genomic amplification of c-*myc* as compared with normal cells.[104,105] This observation was the first reported example of amplification of a cellular oncogene in any human malignancy. This c-*myc* amplification was also present in the fresh, uncultured leukemic cells of the patient from whom the HL-60 cell line was derived, indicating that this amplification did not arise during prolonged in vitro culture.[105] This c-*myc* amplification exhibited by HL-60 appears to be unusual among human hematopoietic malignancies. In a survey of >100 fresh human leukemias and lymphomas, Rothberg et al noted only one other hematopoietic malignancy (a Burkitt lymphoma) that exhibited genomic amplification of c-*myc*.[106]

In correlation with this genomic c-*myc* amplification, HL-60 cells exhibit high levels of steady state c-*myc* RNA. These levels significantly decrease as HL-60 cells are induced to differentiate terminally with granulocytic inducers.[107] In addition, monocytic and macrophagelike differentiation of HL-60 is associated with a marked decrease in c-*myc* RNA levels.[108,109] This decreased c-*myc* expression in differentiating HL-60 cells appears to mimic that which occurs in normal hematopoiesis since a similar decrease in c-*myc* RNA has been noted in normal bone marrow progenitor cells undergoing terminal differentiation in liquid suspension culture.[110]

Decreased c-*myc* transcription rather than enhanced c-*myc* mRNA degradation appears to account for the diminished steady-state c-*myc* RNA in differentiated HL-60.[111-113]

In retinoic acid-treated HL-60 this transcriptional downregulation occurs as a block in elongation of the *myc* RNA transcript between exons 1 and 2 rather than as decreased transcript initiation.[112] This novel mechanism of transcriptional downregulation might be particularly adapted to genes in which transcription is rapidly regulated and HL-60 cells provide the prototype model for studying this phenomenon.

N-ras. HL-60 genomic DNA is capable of malignantly transforming NIH3T3 cells in transfection assays, and the HL-60 gene that mediates this transformation has been identified as the N-*ras* gene,[114] a member of the *ras* family of oncogenes which also includes Kirsten and Harvey *ras*. Acquisition of NIH3T3-transforming ability frequently is associated with specific point mutations within the *ras* oncogenes, and a point mutation involving the second nucleotide of N-*ras* codon 61 has been documented in HL-60.[115] Other acute myeloid leukemia cells exhibit NIH3T3-transforming activity and N-*ras* point mutations.[116–118] In contrast to HL-60, these mutations usually involve N-*ras* codons 12 and 13.[116]

The normal cell function of the N-*ras* cellular oncogene is presently unknown. Why acute myeloid leukemia cells preferentially exhibit mutations in this particular *ras* gene rather than in other members of the *ras* gene family is also unclear. In contrast to c-*myc* gene expression, expression of the N-*ras* gene does not appear to change significantly as HL-60 cells are induced to differentiate. An approximately twofold decrease in N-*ras* RNA was noted in DMSO-differentiated HL-60,[119] whereas no change in N-*ras* expression was noted in TPA-treated HL-60 cells.[109]

p53. The p53 protein is frequently found at elevated levels in various types of tumor cells. This protein shares some characteristics with the c-*myc* product. Both are localized to the nucleus, and p53 can substitute for *myc* in the *myc–ras* cooperative transformation of primary rodent fibroblast cultures.[120,121] The p53 locus is on the short arm of chromosome 17,[122] and this gene is extensively deleted in HL-60 associated with absent p53 expression.[123] Moreover, the opposite p53 allele is absent, presumably secondary to the monosomy 17 that has been demonstrated in HL-60 metaphases.[4] The selective advantage if any of this p53 deletion is unknown. Because c-*myc* and p53 may share similar physiologic functions, it has been suggested that loss of p53 in progenitors of HL-60 may have led to the subsequent selection of cells harboring amplification of c-*myc*.[123]

Although the expression of cellular oncogenes was initially presumed to be associated with actively proliferating cells, some recent rather surprising observations indicate that expression of some cellular oncogenes is enhanced in certain terminally differentiated cells. Examples of this in HL-60 involved the *fos*, *fms*, *src* and *fgr* oncogenes.

c-fos. The c-*fos* gene is the homolog of v-*fos*, the transforming gene of the FBJ-murine sarcoma virus, which induces osteosarcomas in mice. The c-*fos* gene product is localized in the nucleus.[124] Mitogen stimulation of resting fibroblasts induces the rapid (within 5 to 10 minutes) onset of c-*fos* mRNA and protein product, suggesting that c-*fos* may play a role in rendering resting cells competent to divide.[125–127] It is somewhat paradoxical then that a similar rapid induction of c-*fos* is noted when HL-60 cells are treated with TPA,[128,129] since this compound also induces a rapid, pronounced inhibition of HL-60 proliferation.[61,62] Enhanced c-*fos* expression has also been noted during the monocytic differentiation of the mouse WEHI-3B cell line,[130] as well as in normal monocytes and macrophages.[131] Moreover, HL-60 cells induced to monocytes with vitamin D_3 also exhibit enhanced *fos* expression, although such *fos* expression occurs more gradually without the rapid initial c-*fos* expression noted in TPA-treated HL-60.[132] The role that c-*fos* plays in monocyte/macrophage differentiation is presently unclear. c-*fos* expression does not appear to be absolutely essential for monocyte differentiation since vitamin D_3 has been noted to induce monocytic differentiation of some HL-60 variant subclones without inducing enhanced c-*fos* expression.[133]

c-fms. The c-*fms* gene is the cellular homolog of the transforming gene of the McDonough strain of the feline sarcoma virus. The c-*fms* gene product appears to be identical to the cell membrane receptor for the monocyte/macrophage colony-stimulating factor (CSF-1).[134] HL-60 cells induced to differentiate to monocytes with vitamin D_3 or to macrophagelike cells with TPA express enhanced c-*fms* RNA levels as compared with uninduced HL-60 cells.[109] The kinetics of this enhanced expression is considerably slower than induced c-*fos* expression, with c-*fms* transcripts initially noted ~6 hours after inducer treatment and peaking at 24 to 48 hours following induction.[109] By means of immunologic reagents CSF-1 receptors have been detected on monocyte-induced HL-60 cells, but their numbers appear relatively small when compared with normal monocytes/macrophages (C. Rettermier, personal communication, July, 1986). No enhanced *fms* expression is noted in HL-60 cells treated with granulocytic inducers.[109]

c-src. The c-*src* gene is the cellular homolog of the transforming gene of the Rous sarcoma virus and codes for a cell membrane-associated protein ($pp60^{c\text{-}src}$) with tyrosine kinase activity. The levels of $pp60^{c\text{-}src}$ kinase activity are increased in HL-60 cells induced to macrophages, monocytes, or granulocytes with TPA, vitamin D_3, and DMSO, respectively.[135] Normal nonleukemic monocytes also exhibit relatively high levels of $pp60^{c\text{-}src}$ activity.[135] Terminally differentiated rat CNS neurons similarly exhibit relatively high levels of c-*src*.[136] The physiologic function of c-*src* in mature myeloid cells and neurons is presently unknown, but the high level of expression of this cellular oncogene in these terminally differentiated cell types indicates that its function is probably unrelated to active cell proliferation.

c-fgr. c-*fgr* is the cellular homolog of the transforming gene of the Gardner-Rasheed feline sarcoma virus. This gene is a member of the *src* family of oncogenes and codes for a cell membrane-associated protein with tyrosine kinase activity.[137] This gene is expressed in peripheral blood leukocytes with preferential expression in mature monocytes and granulocytes and little expression in B and T lymphocytes. Induction of HL-60 granulocytic differentiation is associated with a marked increase in the level of expression of c-*fgr* (K.

Robbins, personal communication, July, 1986). As with c-*src*, the physiologic function of c-*fgr* in the terminally differentiated HL-60 cells is presently unknown.

SUMMARY AND FUTURE STUDIES

How closely does the in vitro HL-60–induced differentiation mimic normal granulocyte/monocyte/macrophage differentiation? As emphasized above, differences exist between the induced HL-60 cells and normal granulocytes and monocytes. Whether this reflects an intrinsic defect in the karyotypically abnormal HL-60 leukemic cells or represents the failure of such in vitro manipulations to mimic the normal in vivo hematopoietic environment is unknown. A related question is whether the bipotential (granulocyte/monocyte) nature of the HL-60 promyelocytes has its counterpart in normal promyelocytes. Granulocytes and monocytes clearly share a common stem cell, as evidenced by the frequent observation of mixed granulocyte/monocyte colonies in CFU-c assays. This stem cell, however, is generally believed to be more immature than the heavily granulated, peroxidase-positive promyelocyte, whose progeny are usually assumed to be granulocytes. The behavior of HL-60 promyelocytes suggests that the normal promyelocyte may also be capable of differentiating to monocytes. In this regard, it is noteworthy that studies in which HL-60 cells are treated sequentially with granulocytic (retinoic acid) and monocytic (vitamin D_3) inducers indicate that early events in the induction of HL-60 promyelocytes to granulocytes or monocytes are shared by cells of both lineages.[138] Nevertheless, the caveat remains that the leukemic HL-60 promyelocyte is aberrant and does not truly reflect the differentiative potential of normal promyelocytes.

The synergistic effect of various naturally occurring compounds, including retinoic acid, tumor necrosis factor, DIFs, and the interferons on HL-60 cells may reflect some of the normal control mechanisms involved in hematopoiesis. Although the usual in vitro hematopoietic stem cell agar assays generally exploit the effect of single compounds such as CSF or erythropoietin on stem cell proliferation and differentiation, the situation in vivo is undoubtedly more complex. Normal hematopoietic stem cell proliferation and differentiation probably results from a complex array of synergistic inhibitory and stimulatory signals provided by lymphokines, monokines, vitamins, corticosteroids, interferons, and the various CSFs. HL-60 cells provide a convenient system for assessing the synergistic effect of such biologic response modifiers on granulocyte/monocyte/macrophage differentiation.

What is the relation between TPA-induced HL-60 and normal monocyte/macrophage differentiation? TPA is a plant derivative that appears to mimic the effect of naturally occurring compounds such as diacyglycerol in activating the protein kinase C family of enzymes. Conceivably, TPA is not so selective as such endogenous activators of these enzymes and might simultaneously activate a number of different cellular enzymes and targets. This "sledgehammer" effect might account for the unusual macrophagelike phenotype exhibited by TPA-treated HL-60 cells. TPA is a very active membrane stimulator and induces oxidase activity, chemiluminescence, and degranulation in both normal and induced HL-60 monocytes and macrophages. Such membrane effects may also be mediated through protein kinase C.[139,140] TPA may simultaneously induce both differentiation and membrane activation of HL-60 cells to account for the unusual phenotype of TPA-treated HL-60.

The recent isolation and analysis of protein kinase C cDNA clones indicates that at least three distinct types of this enzyme are present in mammalian species and that expression of these different enzymes varies from tissue to tissue.[141-143] It will be of interest to determine the distribution of these different protein kinase C enzymes in uninduced *v* induced HL-60 cells. Conceivably, these various protein kinases may act on different substrates, may have different affinities for TPA, and may be differentially distributed in uninduced *v* induced HL-60. This might account for the different phenotypic changes induced in HL-60 by different concentrations of TPA and might also explain the different effects induced by TPA depending on the state of differentiation of the HL-60 cells.

The pronounced antiproliferative effect of TPA on HL-60 is of particular interest and could have therapeutic relevance, since a similar TPA-induced effect is also noted in most fresh acute myelogenous leukemia cells. The adverse effects (including tumor promotion) exerted by TPA on other cell types, however, rules out its current use as a therapeutic agent.[144] Future studies attempting to define the specific HL-60 TPA targets that trigger this growth inhibition should provide a greater understanding of the antiproliferative effects of TPA and may lead to more selective therapeutic agents for myeloid leukemia.

The HL-60 cell line, because of its distinct monocyte/granulocyte characteristics, will continue to provide a ready source of specific human mRNA for use in cloning important granulocyte and monocyte enzymes and monokines. Examples of such monocyte/granulocyte specific clones derived from HL-60 to date include the gene for tumor necrosis factor (cachectin) cloned from a TPA-treated HL-60 cDNA library[145] and the candidate gene that is defective in chronic granulomatous disease, cloned from a granulocyte-induced HL-60 cDNA library.[146]

HL-60 cells exhibit structural abnormalities of at least three different cellular oncogenes (c-*myc*, N-*ras*, and p53) and one hematopoietic growth factor (GM-CSF). How such mutations are related to the continuous proliferation and block in differentiation exhibited by HL-60 is an area of active investigation. Of particular experimental interest is the relationship between the HL-60 c-*myc* amplification and this block in differentiation. Does the induction of decreased levels of c-*myc* RNA per se lead to differentiation of HL-60 cells or are other direct or indirect effects of differentiation inducers on other HL-60 genes required: An "antisense" 15-base pair (bp) oligonucleotide complementary to the translation initiation region of c-*myc* was recently noted to induce differentiation of HL-60 cells (J. Holt, personal communication, December, 1986). The control "sense" oligomer was ineffective in inducing such differentiation. These observations are preliminary but suggest that the c-*myc* product is critical to maintaining HL-60 cells in a relatively undifferentiated proliferative state and that inhibition of this product alone may result in the terminal differentiation of HL60 cells. The normal physiologic function of most of the cellular oncogenes remains to be defined. Particularly perplexing are those oncogenes such as *fgr, fos,* and *src* whose expression is enhanced in certain terminally differentiated rather than actively proliferating cells. How closely HL-60 leukemic cell differentiation mimics the differentiation of normal myeloid progenitor cells is presently unclear, and significant differences between the mechanisms of HL-60 and normal myeloid progenitor cell differentiation may exist. Nevertheless, the specific changes in *myc, fos, fgr,* and *src* cellular oncogene expression that characterize HL-60 cell differentiation also appear to occur during normal myeloid cell differentiation. Thus, HL-60 cells should continue to provide an excellent model system for studying both the regulation of expression of these cellular oncogenes and the physiologic role these particular genes play in the terminal differentiation of normal monocytes, macrophages, and granulocytes.

REVIEW ARTICLE

Hemoglobin S Gelation and Sickle Cell Disease

By William A. Eaton and James Hofrichter

THE FUNDAMENTAL cause of sickle cell disease is the decreased deformability of the sickled red cell produced by gelation of hemoglobin S. Partial inhibition of gelation should therefore reduce clinical severity, while complete inhibition should result in a "cure." These basic ideas have stimulated an enormous effort to understand the gelation process in detail and to relate the results of these studies to the pathophysiology of sickle cell disease. Discoveries concerning gelation have also led to new lines of research on a specific therapy. The early finding that fetal hemoglobin inhibits gelation.[1,2] has ultimately led to the development of methods to increase the production of F cells in the bone marrow of sickle cell patients,[3-5] while the discovery of the enormous sensitivity of the rate of gelation to hemoglobin concentration[6] has stimulated studies on the reduction of intracellular hemoglobin concentration as a means of therapy.[6-12] Studies on the structure of the hemoglobin S polymer,[13-18] moreover, have guided the development of agents designed to inhibit gelation by interfering with the formation of intermolecular contacts in the polymer.[19-21]

The purpose of this article is to review recent developments in the relation between hemoglobin S gelation and sickle cell disease. We first present our current understanding of the major features of the gelation process. Since gelation is a physical rather than a chemical process, its description necessarily requires more physical detail than that of most biological processes. From these studies we are able to develop a more rigorous and comprehensive description of the relation between gelation and the pathophysiology than has been possible up to now. By combining the gelation studies with work on the rheology of sickle cells and blood flow in the microvasculature, a clearer picture emerges of the outstanding issues in understanding the mechanism of vaso-occlusion in patients and the resulting cardiovascular response. Finally we discuss the variation in clinical severity and analyze the problem of inhibiting gelation in patients. Throughout this discussion we shall see that the kinetics of gelation is a dominant factor in understanding gelation both in vitro and in vivo, and it will become clear that discussions of the pathophysiology that do not include a kinetic analysis[22,23] are inadequate.

A broader treatment of sickle cell disease, including genetic and clinical aspects, has recently appeared in two excellent books.[24,25] Also the structure, physical chemistry, and rheology of hemoglobin S gelation in solution and in red cells is discussed much more extensively in an article that is being published elsewhere.[26]

GELATION AT EQUILIBRIUM

To understand gelation we first must describe a gel at equilibrium. As shown in Fig 1, a gel can be separated into two phases, a solution phase that contains free hemoglobin molecules and a polymer phase. The structure of the individual polymers has now been determined in considerable detail. It is a fiber made up of 14 intertwined helical strands of hemoglobin S molecules.[14,15,27] The fiber can alternatively be described in terms of seven intertwined double strands of molecules in which the double strands have a structure that, except for a slight helical twist, is nearly identical to the double strands that form the fundamental unit of the deoxyhemoglobin S single crystal.[16,28,29] In each molecule one of the two $\beta 6$ valines of the $\alpha_2\beta_2$ tetramer is involved in an intermolecular contact with its neighbor in the double strand. The structure of the deoxyhemoglobin S crystal is known to atomic resolution, so that there is a very detailed picture of the intermolecular contacts within the double strand that must be very similar to what occurs in the polymer.[16-18]

A gel at equilibrium behaves very much like a suspension of microscopic protein crystals suspended in a saturated protein solution.[30-32] The concentration of hemoglobin in the solution phase, which is called the solubility, is an accurate measure of the stability of the polymer phase. The solubility is determined experimentally by measuring the hemoglobin concentration in the supernatant obtained after high-speed sedimentation of the polymers.[31-36] Because the concentration of hemoglobin in the polymer phase appears to be relatively constant,[37] the fraction of the total hemoglobin that is polymerized can be calculated from the solubility using a simple mass conservation relation. There have now been systematic investigations of the solubility under a wide variety of solution conditions. These include the dependence on temperature,[31,32,35] pH,[38,39] salts,[40] 2,3-DPG,[39,41,42] carbon monoxide,[36,43,44] oxygen,[45,46] and non-S hemoglobins.[30,37,38,47-63]

The role of non-S hemoglobins in the gelation of hemoglobin mixtures has been the focus of a large number of studies, since early investigations showed that the presence of hemoglobins A, C, and F reduces sickling and is accompanied by decreased clinical severity.[25] For mixtures of hemoglobins S and F (and $S + A_2$), a detailed analysis of solubility data, including the large contribution of nonideality arising from excluded volume effects,[32,37,54,55] indicates that over the physiologic range of compositions there is little or no copolymerization of either the homotetramers, $\alpha_2\gamma_2$ (and $\alpha_2\delta_2$), or the hybrid tetramers, $\alpha_2\beta^S\gamma$ (and $\alpha_2\beta^S\delta$).[26,37,64] The low probabilities for copolymerization of these molecules can be rationalized as resulting from destabilizing effects on the intermolecular contacts of the double strand that accompany specific

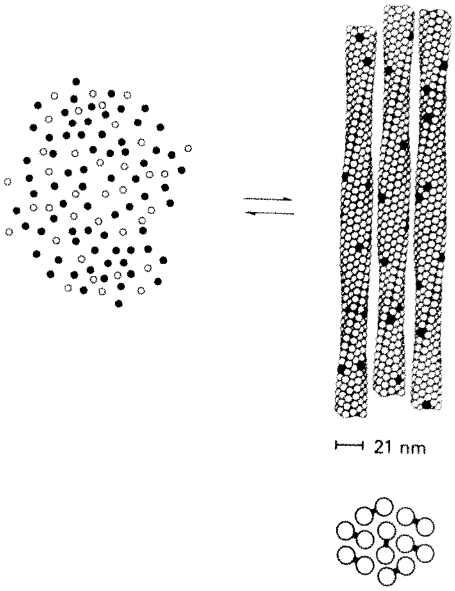

Fig 1. Schematic picture of a gel of hemoglobin S at partial saturation with oxygen. The 64 kD molecule (ie, the tetramer) is represented as a circle. A gel of hemoglobin S contains large polymers, often called fibers, and a concentrated solution of free hemoglobin molecules. The filled circles represent hemoglobin S molecules with one or more oxygen molecules bound. There are relatively fewer filled circles in the polymer because it has a lower oxygen affinity than the solution. The structure was determined by Edelstein and coworkers using electron microscopy and image reconstruction techniques.[14,15] The cross-section shows that the fiber consists of 14 strands and that it can be constructed from seven double strands that are very similar to those found in the deoxyhemoglobin S single crystal.[18,27,29]

amino acid replacements on the molecular surface.[37,65] For S + A and S + C mixtures the analysis indicates that there is little or no copolymerization of the $\alpha_2\beta_2^A$ and $\alpha_2\beta_2^C$ molecules but that the hybrid molecules $\alpha_2\beta^S\beta^A$ and $\alpha_2\beta^S\beta^C$ copolymerize with a probability that is approximately half that for $\alpha_2\beta_2^S$.[26,37,62] The factor of 2 is consistent with the structural result that a valine residue is required at only one of the two $\beta 6$ sites on each molecule for it to be incorporated into the polymer.

Binding of oxygen to hemoglobin S has a dramatic effect on gelation. Experiments performed over 35 years ago demonstrated that fully deoxygenated hemoglobin S gels, while fully oxygenated hemoglobin S does not.[66] To begin to consider the pathophysiology of sickle cell disease, however, it is clear that one needs quantitative data on solutions that are partially saturated with oxygen, particularly over the range of fractional saturations encountered in vivo. Such data have been obtained only relatively recently. The schematic picture of gelation in Fig 1 points out several important questions that must be answered regarding gelation in the presence of oxygen. These include (1) what is the fraction of hemoglobin molecules that are polymerized? and (2) what are the fractional saturations with oxygen of the molecules in the solution and polymer phases? The fraction polymerized can be determined from measurements of the solubility as a function of solution phase saturation.[46] Also, because there is no aggregation in the solution phase of the gel[67,68] and the $\beta 6$ mutation has no effect on the intrinsic affinity of the hemoglobin molecule, the binding curve for the solution phase hemoglobin S molecules is normal.[69,70] The major problem has been to obtain the polymer binding curve, which was accomplished using an optical technique called linear dichroism.[14,46,71-73]

The principal experimental results are shown in Fig 2. The solubility increases slowly at low oxygen saturation, then increases sharply at high saturations (Fig 2 b). The most interesting finding from the binding studies is that the polymer binds oxygen noncooperatively, as evidenced by a slope of unity in a Hill plot.[46] The two-state allosteric model,[74] which has provided an excellent framework for interpreting a wide variety of experiments on hemoglobin, provides a simple molecular interpretation of these results.[46] According to this model a hemoglobin molecule free in solution exists in one of two affinity states at all stages of oxygenation. The low-affinity state, called T, has the quaternary structure of completely deoxygenated hemoglobin, while the high-affinity state, called R, has the quaternary structure of the fully oxygenated molecule. Binding to either quaternary structure is noncooperative. Cooperativeness arises from the continuous conversion of low-affinity T-state molecules to high-affinity R-state molecules as the saturation increases (Fig 2 a). The simplest extension of this model to the gelation of hemoglobin S is to postulate that all T-state molecules polymerize with equal probability independent of the number of oxygen molecules bound and that there is no polymerization of R-state molecules.[46] The model is based on the idea that R-state molecules do not polymerize because their structure is sufficiently different from T-state molecules that they cannot fit into the polymer lattice. Analysis of the structure of the double strand of the deoxyhemoglobin S crystal does indeed show that it is impossible to replace the T-state molecule with an R-state molecule.[18] Since the polymer contains only T-state molecules, the model predicts that it will bind oxygen noncooperatively, exactly as observed. The model is not quantitatively perfect, however, because the affinity of the polymer is slightly lower than that of solution T-state molecules (Fig 2 a). Evidence for this small difference is also found in the solubility data (Fig 2 b), indicating that T-state molecules with oxygen bound are partially discriminated against by polymers. The small conformational changes that are known to take place within the T quaternary structure upon oxygen binding could explain this result.[45] The picture that emerges, then, is that the simplest extension of the two-state allosteric model provides an excellent description of the effect of oxygen on gelation.

The results of these experiments can be used to explain data on polymerization in sickle red cells. The first step is to consider further the oxygen binding curve of a gel. As mentioned above, at a given oxygen pressure the saturation of the gel is a weighted average of the saturations of the solution and polymer phases. Figure 2 c shows gel binding curves under near physiologic conditions that have been constructed from solution and polymer phase binding curves (Fig 2 a) and from the solubility curve (Fig 2 b). As the

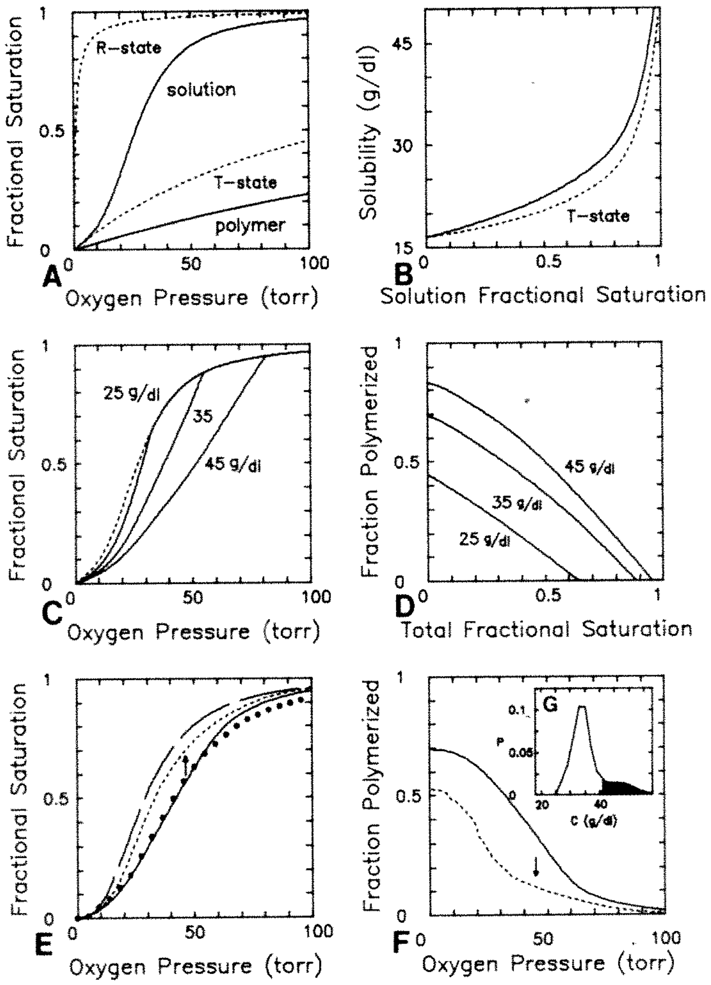

Fig 2. Effect of oxygen on gelation in solution and in sickle cells. (A) Solution, polymer, and theoretical R- and T-state binding curves. The solution binding curve is the binding curve for normal blood. The polymer binding curve is calculated from the data in phosphate buffer of Sunshine et al.[46] The R- and T-state binding curves are theoretical and were obtained by fitting to the solution binding curve with the two-state allosteric saturation function.[74] (B) Solubility as a function of solution-phase saturation and oxygen pressure from the data of Sunshine et al.[46] The dotted curve shows the theoretical solubility for the hypothetical case in which all T-state molecules polymerize with equal probability, independent of the number of oxygen molecules bound. (C) Gel-binding curves at different total hemoglobin concentrations calculated from the results in (A) and (B).[28,46] The dotted curve is the solution binding curve of A. (D) Fraction polymerized as a function of total fractional saturation calculated from the results in (A) and (B).[28,46] (E) In vivo oxygen binding curve calculated for a population of cells having the distribution of intracellular hemoglobin S concentrations in (G). The binding curve calculated in the absence of polymer (long-dashed curve) and the binding curve calculated when polymer is present at equilibrium (solid curve) are shown for reference. The data points are for SS blood from Winslow.[77] The oxygen unloading curve under in vivo conditions (dotted curve) was calculated by requiring that only the densest 18% of the cell population contain polymer at the average venous Po_2 found in SS patients (46 torr)[78] denoted by the arrow. These conditions were simulated by requiring that each cell be sufficiently supersaturated for polymerization to occur within about 200 ms at each Po_2. (F) Fraction of total hemoglobin S that is polymerized. The fraction is calculated under equilibrium conditions (curve) and under in vivo conditions (dotted curve). (G) The average distribution of intracellular concentrations from a study of 43 patients by Fabry et al[75] used in the calculations in panels (E) and (F). The probability density, P, in dL/g is plotted *v* the intracellular hemoglobin concentration, C, in g/dL. The blackened area shows the subpopulation of cells that contain polymer at Po_2 of 46 torr. The equations and parameters used in the calculation of all of the above panels are given by Eaton and Hofrichter,[28] which are derived from the work of Sunshine et al.[46]

oxygen pressure increases, not only do the saturations of both phases increase but the solubility also increases, decreasing the contribution of the low affinity polymer phase to the total binding curve. As a result the gel binding curves appear to have lower-than-normal affinity with higher-than-normal cooperativeness.[44] At sufficiently high oxygen pressures the solubility exceeds the total hemoglobin concentration, and the binding curve superimposes on the normal solution binding curve (Fig 2 c). As the total hemoglobin concentration increases, the affinity of the gel decreases owing to the increased fraction of the low affinity polymer (Fig 2d), and the oxygen pressure at which the polymer disappears also increases.

The oxygen-binding curve of a single red cell should be identical to the binding curve of a gel having the same composition (total hemoglobin S concentration, fraction fetal hemoglobin, pH, 2,3-DPG concentration, etc). Oxygen-binding curves of sickle blood are an average of the gel-binding curves for the individual cells. As in gels, the binding curve for sickle blood is "right shifted" compared to normal blood. Although 2,3-DPG levels are elevated in sickle cell blood, the formation of the low-affinity polymer is the major cause of the right shift in the blood-binding curve.[77,79]

The major difference between the binding curves for cell suspensions (Fig 2 e) and for gels (Fig 2 c) results from the wide distribution of hemoglobin S concentrations, which varies from about 20 g/dL in F cells to almost 50 g/dL.[79-81] This distribution produces a wide range of median affinities within the red cells from a given patient and hence smears the characteristic features of the gel-binding curve (compare Figs 2 c and 2 e). To calculate blood-binding curves it is necessary to utilize the results of recent investigations that have characterized the distribution of total hemoglobin concentrations from density measurements.[62,75,76,82-88] The density distributions for SS cells are broader and more variable than those for normal individuals. Since the distribution of intracellular hemoglobin S and hemoglobin F concentrations was not determined for the cells employed in the oxygen-binding measurements, it is only possible to make qualitative comparisons between the observed binding curves and those calculated from solution data. Figure 2 e compares a whole blood oxygen-binding curve with the binding curve calculated from the solution data using the average concentration distribution from a study of 43 patients.[26,75] The p50s for the curves calculated from concentration distributions for individual patients vary from 37 torr to 46 torr, compared to the 33 torr to 45 torr observed in a study of 14 patients.[77,89] This comparison shows that the patient-to-patient variability in oxygen binding curves can be readily accounted for by the variability in intracellular concentration distributions. A more direct comparison on a relatively homogeneous cell population obtained by density fractionation, in which the 2,3-DPG and hemoglobin F levels were also measured, gives very good agreement between the cell and solution data.[26,79]

Gelation in isolated solutions and cells has also been compared using nuclear magnetic resonance techniques to measure the average fraction of polymerized hemoglobin as a function of the total saturation of the cells.[76,90-92] The nuclear magnetic resonance measurements take advantage of the fact that the polymerized molecules do not rotate freely, making it possible to selectively measure the spectra of the polymerized and unpolymerized molecules.[93] Measurements on a cell population of known concentration distribution are in good agreement with the curve calculated from the solution data.[76] Agreement is also obtained in a comparison of density fractionated cells, although the experimental uncertainties are much larger.[76]

At this point we should emphasize that the oxygen binding curves and polymer fraction curves that we have discussed are equilibrium or near-equilibrium curves and, as we shall see later, are very different from the in vivo situation in which most cells are very far from equilibrium because of the large kinetic effect of the delay time (Fig 2 e and 2 f).

KINETICS AND MECHANISM OF GEL FORMATION

The most unusual and interesting aspect of the gelation process is the kinetics and mechanism of gel formation. The simplest kinetic experiment takes advantage of the characteristic property that a hemoglobin S solution gels upon heating. A completely deoxygenated solution, having a concentration significantly less than the solubility at 0°C (< 30 g/dL), is heated to some temperature where the concentration exceeds the solubility. Polymer formation can be detected by a variety of techniques, including linear birefrin-

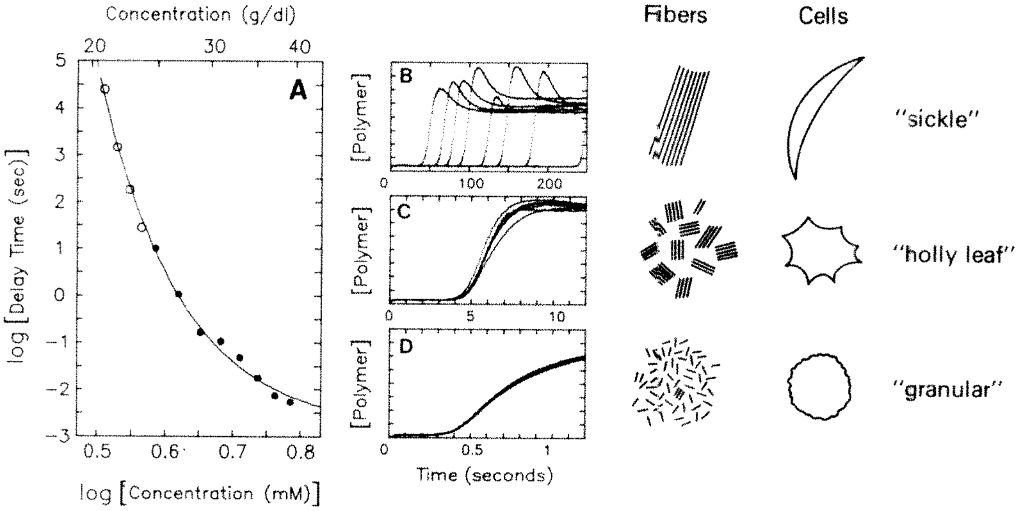

Fig 3. Kinetics of gelation and morphology of cells. (A) Concentration dependence of the delay time from laser photolysis (filled circles) and temperature-jump measurements (open circles; from Ferrone et al[132]). (B, C, D) Reproducibility of kinetic progress curves for samples having different delay times (from Hofrichter[133]). The schematic at the right shows that in a slowly polymerizing cell the "sickle" morphology is postulated to result from the formation of a single domain of well-aligned fibers; that in a more rapidly polymerizing cell the "holly leaf"morphology results from the formation of a number of smaller domains of shorter, aligned fibers; and that in the fastest polymerizing cells the "granular" morphology results from the formation of a large number of very small domains or randomly oriented short fibers.

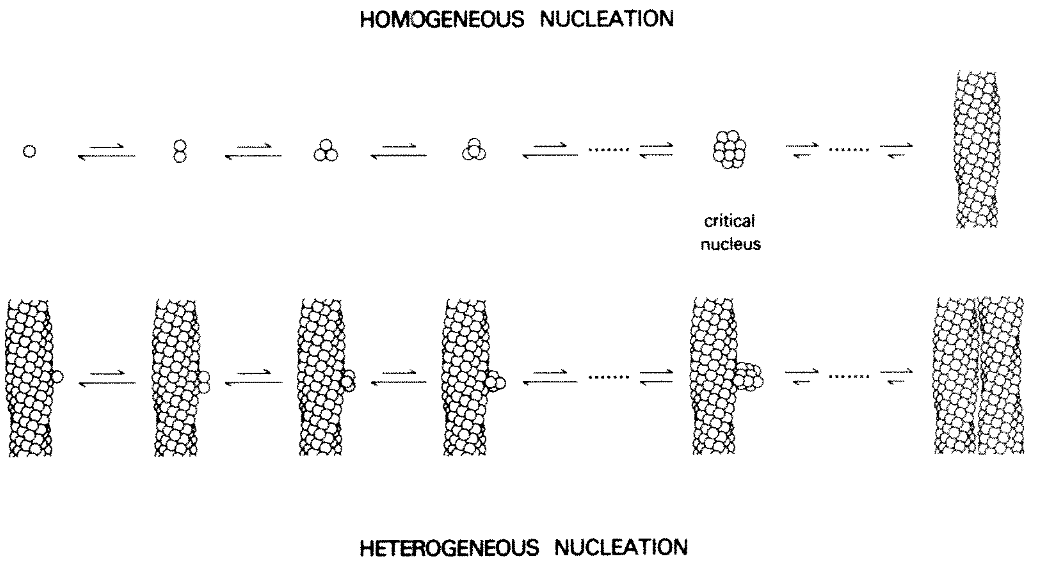
gence,[6,43,45,94] turbidity,[36,37,43,44,57,95-112] light scattering (G.W. Christoph and R.W. Briehl, unpublished results),[113-115] viscosity,[59,112,116-122] water proton magnetic resonance linewidths[123] and transverse relaxation times,[124-128] and electron paramagnetic resonance.[129] All of the techniques show the same type of time course. There is an apparent delay period during which there is no evidence for any aggregation, followed by the explosive appearance of polymer.[6,94,95,116,130] Upon lowering the temperature of a preformed gel, depolymerization proceeds much more rapidly and without a delay.[6,94,95] The most striking finding from these studies is that the delay time is enormously sensitive to solution conditions, in particular to the hemoglobin S concentration. The inverse of the delay time is found to be proportional to the 30th to 50th power of the initial hemoglobin concentration.[6,36,37] This is the highest known concentration dependence for a process taking place in solution. The delay time is also found to be directly proportional to the 30th to 45th power of the solubility, independent of the manner in which the solubility is altered.[36,97] For example, in temperature-jump experiments, the delay time for a solution that is 10% saturated with carbon monoxide is increased by a factor of about 10 relative to deoxyhemoglobin S at the same total hemoglobin concentration, and at a saturation of 40% the delay time is increased by a factor of about 10^4.[36,44]

The temperature-jump technique is limited to measuring delay times longer than about 100 seconds. To extend the kinetic measurements to physiologic times and hemoglobin concentrations required the development of a laser photolysis technique that could be used to prepare a completely deoxygenated hemoglobin S solution in less than a few milliseconds.[131-133] In this technique the carbon monoxide complex of hemoglobin S, which is soluble up to at least 48 g/dL,[134] can be converted to deoxyhemoglobin S by photodissociation under continuous laser illumination. The laser also serves as a source for monitoring gel formation from the change in light scattering. When the laser is turned off, the carbon monoxide recombines, the polymer disassembles to form a solution of monomers (ie, 64 kD hemoglobin S tetramers), and the experiment can be repeated indefinitely. Because the volumes of observation are as small as 10^{-11} cc, the laser photolysis technique can also be used for investigating gelation in single red cells.[135-137]

A combination of the temperature jump and laser photolysis techniques has been used to examine the kinetics of gelation over a wide range of concentrations, temperatures, and times.[132] Figure 3 shows that as the concentration decreases, the delay time increases from about 10 milliseconds at 40 g/dL to about 100,000 seconds at 20 g/dL. An important clue to the mechanism by which gelation occurs comes from a very unusual result, discovered in the course of the laser photolysis experiments, which is described in Fig 3. Highly reproducible delay times are observed for solutions with delay times of a few hundred milliseconds or less. When the delay times become longer than a few seconds, however, the delay times become very *ir*reproducible, despite the fact that the progress curves have very similar shapes once polymerization begins (Fig 3 b to d).[131-133] An important companion observation is that only a single birefringent domain of polymers forms when there are large fluctuations



HOMOGENEOUS NUCLEATION

HETEROGENEOUS NUCLEATION

Fig 4. The double nucleation mechanism (Ferrone et al[138]). The two pathways for nucleation of polymers are shown. In the homogeneous pathway nuclei form in the solution, while in the heterogeneous pathway nuclei form on the surface of existing polymers. As more polymers form the increased surface area results in a continuously increasing rate of heterogeneous nucleation. This autocatalytic formation of polymers via the heterogeneous nucleation pathway is responsible for the appearance of a delay period prior to the observation of polymer. For both nucleation pathways there are competing thermodynamic forces. Initially aggregation is unfavorable because entropic forces tend to keep molecules apart. As the nuclei become larger, however, there is an increased number of bonds per monomer, 1/2 for a dimer, 3/3 for a trimer, 6/4 for a tetramer, up to 4.1 in the infinite polymer. As the aggregates grow this increase in the stability from more bonds per monomer finally overcomes the unfavorable entropic forces. The aggregate for which addition of monomer finally becomes favorable is called the critical nucleus.

gence,[6,43,45,94] turbidity,[36,37,43,44,57,95-112] light scattering (G.W. Christoph and R.W. Briehl, unpublished results),[113-115] viscosity,[59,112,116-122] water proton magnetic resonance linewidths[123] and transverse relaxation times,[124-128] and electron paramagnetic resonance.[129] All of the techniques show the same type of time course. There is an apparent delay period during which there is no evidence for any aggregation, followed by the explosive appearance of polymer.[6,94,95,116,130] Upon lowering the temperature of a preformed gel, depolymerization proceeds much more rapidly and without a delay.[6,94,95] The most striking finding from these studies is that the delay time is enormously sensitive to solution conditions, in particular to the hemoglobin S concentration. The inverse of the delay time is found to be proportional to the 30th to 50th power of the initial hemoglobin concentration.[6,36,37] This is the highest known concentration dependence for a process taking place in solution. The delay time is also found to be directly proportional to the 30th to 45th power of the solubility, independent of the manner in which the solubility is altered.[36,97] For example, in temperature-jump experiments, the delay time for a solution that is 10% saturated with carbon monoxide is increased by a factor of about 10 relative to deoxyhemoglobin S at the same total hemoglobin concentration, and at a saturation of 40% the delay time is increased by a factor of about 10^4.[36,44]

The temperature-jump technique is limited to measuring delay times longer than about 100 seconds. To extend the kinetic measurements to physiologic times and hemoglobin concentrations required the development of a laser photolysis technique that could be used to prepare a completely deoxygenated hemoglobin S solution in less than a few milliseconds.[131-133] In this technique the carbon monoxide complex of hemoglobin S, which is soluble up to at least 48 g/dL,[134] can be converted to deoxyhemoglobin S by photodissociation under continuous laser illumination. The laser also serves as a source for monitoring gel formation from the change in light scattering. When the laser is turned off, the carbon monoxide recombines, the polymer disassembles to form a solution of monomers (ie, 64 kD hemoglobin S tetramers), and the experiment can be repeated indefinitely. Because the volumes of observation are as small as 10^{-11} cc, the laser photolysis technique can also be used for investigating gelation in single red cells.[135-137]

A combination of the temperature jump and laser photolysis techniques has been used to examine the kinetics of gelation over a wide range of concentrations, temperatures, and times.[132] Figure 3 shows that as the concentration decreases, the delay time increases from about 10 milliseconds at 40 g/dL to about 100,000 seconds at 20 g/dL. An important clue to the mechanism by which gelation occurs comes from a very unusual result, discovered in the course of the laser photolysis experiments, which is described in Fig 3. Highly reproducible delay times are observed for solutions with delay times of a few hundred milliseconds or less. When the delay times become longer than a few seconds, however, the delay times become very *ir*reproducible, despite the fact that the progress curves have very similar shapes once polymerization begins (Fig 3 b to d).[131-133] An important companion observation is that only a single birefringent domain of polymers forms when there are large fluctuations

Fig 4. The double nucleation mechanism (Ferrone et al[138]). The two pathways for nucleation of polymers are shown. In the homogeneous pathway nuclei form in the solution, while in the heterogeneous pathway nuclei form on the surface of existing polymers. As more polymers form the increased surface area results in a continuously increasing rate of heterogeneous nucleation. This autocatalytic formation of polymers via the heterogeneous nucleation pathway is responsible for the appearance of a delay period prior to the observation of polymer. For both nucleation pathways there are competing thermodynamic forces. Initially aggregation is unfavorable because entropic forces tend to keep molecules apart. As the nuclei become larger, however, there is an increased number of bonds per monomer, 1/2 for a dimer, 3/3 for a trimer, 6/4 for a tetramer, up to 4.1 in the infinite polymer. As the aggregates grow this increase in the stability from more bonds per monomer finally overcomes the unfavorable entropic forces. The aggregate for which addition of monomer finally becomes favorable is called the critical nucleus.

inside sickle cells proceeds at the same rates and by the same mechanism as in purified solutions. Several results indicate that the answer is *yes*. First, studies on the addition of red cell membrane components to deoxyhemoglobin S solutions show little or no effect on the delay time.[110,111] Second, the laser photolysis technique has permitted the measurement of the kinetics of gelation in single red cells, yielding results that are in qualitative agreement with those predicted from the solution studies.[135] The shapes of the kinetic progress curves are very similar to those observed in solution,[135-137] and for slowly polymerizing cells there are the expected stochastic fluctuations in the delay times.[135] Figure 6 shows that the distribution of observed delay times, which range from a few milliseconds to over 100 seconds, is almost exactly what is predicted from the solution studies and the known concentration heterogeneity. A more detailed comparison of solution and cell data can be made by calculating the intracellular hemoglobin S concentration distribution from the delay time distribution using the solution delay times. The calculated distribution in Figure 6 is qualitatively the same as the measured distributions (Figure 2g), showing that there are no major differences in the rates of gelation in solution and in cells.

SICKLING AS AN INDICATOR OF INTRACELLULAR GELATION

While it has long been accepted that the deformation of SS red cells upon complete deoxygenation is caused by intracellular polymerization,[66] the detailed relation between gelation and cell deformation has remained somewhat ambiguous. In this section we address two questions. The first is whether or not there is a well-defined relationship between cell shape and intracellular polymerization. The second is whether the wide variety of observed cell shapes can be rationalized in terms of what we now know about the kinetics and thermodynamics of gelation. The answers to these questions are important, since a direct link between cell morphology and polymerization would permit a variety of experiments to be performed by using morphological criteria in place of more complex and difficult physical measure-

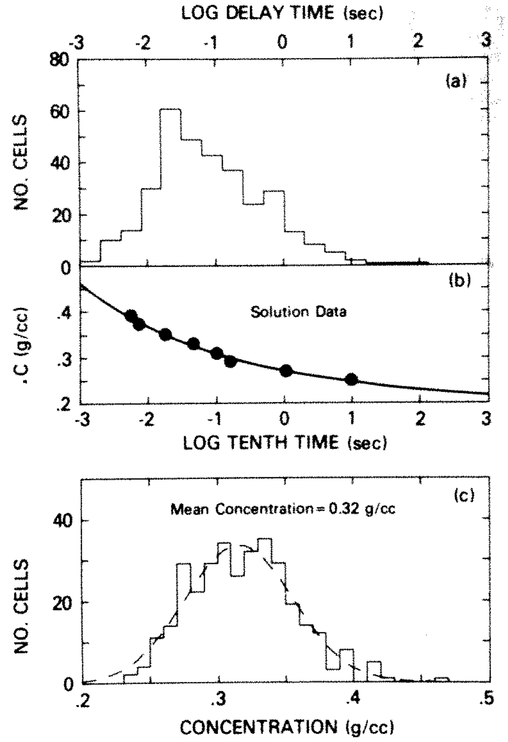

Fig 6. **Distribution of delay times for deoxyhemoglobin gelation in individual cells (from Coletta et al[135]). (A) Distribution of delay times from three homozygous SS patients. (B) Relation between concentration and logarithm of tenth time from solution data (Fig 3). (C) Intracellular hemoglobin S concentration distribution determined by calculating the concentration corresponding to each delay time in (A) using the result in (B). The intracellular hemoglobin S concentration is somewhat underestimated because the delay times in potassium phosphate buffer are shorter than in physiologic buffer (P.L. San Biagio, J. Hofrichter, and W.A. Eaton, unpublished results).**

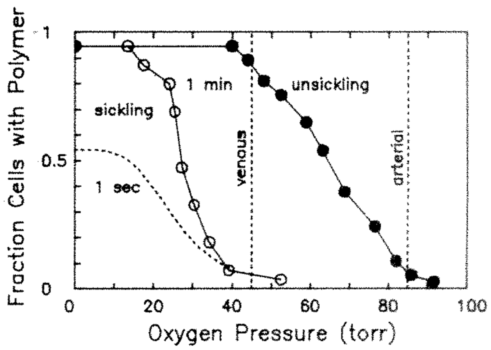

Fig 7. **Fraction of cells containing polymer as a function of calculated oxygen pressure determined by a double laser beam photolysis technique (from Mozzarelli et al[136,137]). In this technique one laser beam illuminating a single red cell is used to prepare hemoglobin S at a steady-state partial saturation with carbon monoxide by continuous photodissociation, while a second more intense laser beam can be switched on at any time to completely photodissociate the remaining carbon monoxide and to measure the kinetics of gelation from the time course of the scattered laser light. If no polymerized hemoglobin is present in the cell at partial saturation, the kinetics of gelation at zero saturation (produced by the second laser beam) are characterized by a delay period, while the presence of polymerized hemoglobin is indicated by the loss of the delay period. Experiments on hemoglobin S solutions show that this technique accurately simulates the gelling behavior of hemoglobin S at partial saturation with oxygen and that the presence of as little as 0.05% polymerized hemoglobin results in a marked shortening of the delay period. The oxygen pressures were calculated from the measured saturations with carbon monoxide using the least squares fit of the two-state allosteric saturation function to the binding curve of normal blood. The filled circles are the equilibrium data obtained in reoxygenation (ie, resaturation with carbon monoxide) experiments, the open circles are data obtained from experiments where deoxygenation (desaturation) is carried out over a period of one minute, and the dashed curve is a theoretical estimate for deoxygenation carried out in one second.[141] The vertical dashed lines indicate the average oxygen pressure found in the arteries and veins of patients with homozygous SS disease.[78]**

ments such as light scattering[135-137] or micropipette measurements.[140]

The relationship between cell deformation and intracellular polymerization has recently been studied with a variation on the laser photolysis technique. Gelation in partially saturated single cells was investigated by using the kinetics of gelation after complete photodissociation as a probe for the presence of polymer (Fig 7).[136,137] The delay time provides a very sensitive probe for polymer because even vanishingly small amounts of polymerized hemoglobin ($< 0.05\%$) drastically reduce or eliminate the delay period.[136,137] These experiments demonstrate clearly that sickling accurately reflects the onset of gelation and that unsickling indicates the complete disappearance of polymer.[136,137] As a result, curves that describe the fraction of cells containing polymer as a function of saturation or oxygen pressure may be designated sickling and unsickling curves. Figure 7 shows the fraction of sickled cells, ie, the cells that contain polymerized hemoglobin S, as a function of the oxygen pressure, calculated from the measured saturation with carbon monoxide. There is a very large hysteresis between the sickling and unsickling curves. The oxygen pressure at which polymers are first observed in deoxygenation experiments in an initially polymer-free cell is always much lower than the pressure at which polymers disappear in reoxygenation experiments.The hysteresis occurs because there is a delay period before polymer can be detected upon deoxygenation, but in reoxygenation experiments depolymerization occurs without any delay period. Thus the unsickling curve is very close to an equilibrium curve, while the sickling curve depends on the rate of deoxygenation. The sickling curve in Fig 7 was measured by lowering the saturation over a period of one minute. In the microcirculation, deoxygenation occurs in about one second; sickling curves have not yet been measured on this time scale. However, the theoretical one-second sickling curve shown in Fig 7 is seen to be extremely left shifted,[141] in qualitative accord with the results of kinetic studies that show that about 50% of cells sickle after about one second at zero oxygen pressure.[142,143] Experiments in which cellular deformation occurs much more rapidly have also been performed by deoxygenating cells in a mixer.[144] These data are consistent with the results on intracellular gelation using the laser photolysis technique,[26,135] suggesting that cell deformation is a reliable indicator of intracellular gelation on the second and subsecond time scale as well.

Essentially identical conclusions have been reached from experiments in which rheologic techniques are used to examine individual sickle cells. The most direct data have come from measurements as a function of oxygen pressure using micropipette techniques.[140] Both the static and dynamic rigidities of the cells can be measured. The static rigidity is characterized by the change in the length of the "tongue" aspirated into the pipette with a change in negative pressure, while the dynamic rigidity is characterized by the half-time required to achieve the final tongue length after initiating the pressure change.[145] For oxygenated cells there are only small increases in these quantities, with the largest increases for the irreversibly sickled cells and the densest cells.[146,147] As the oxygen pressure is decreased, cells are observed to undergo a variety of morphological changes, and cells having a given set of morphological characteristics can be examined.[140] Cells that are "spiculated" or have a "granular" surface show markedly altered rheology. In contrast, discocytes that maintain a "smooth surface" show the same static and dynamic rigidities at all oxygen pressures as normal cells, in agreement with the conclusion from the kinetic studies. In cells showing morphologic evidence of gelation, both the static rigidity and the half-time for tongue growth increase with decreasing oxygen pressure. At the lowest oxygen pressures the static rigidity increases by up to a factor of 100, and the half-time for tongue growth increases by a factor of 150 to 1000 relative to normal cells and oxygenated sickle discocytes.[140,148] Since both parameters are much greater for all cells containing polymerized hemoglobin than for polymer-free cells, it appears that the presence or absence of intracellular polymer is much more important in determining cellular rigidity than the extent of intracellular polymerization.[149]

A closely related problem is to understand the enormous variety of cell shapes that are observed in a population of sickled cells. It has been known for over 45 years that slow deoxygenation results in elongated, birefringent cells, while rapid deoxygenation produces a much less distorted cell, originally called a granular form.[150] An unexpected bonus provided by the double nucleation mechanism is that it suggests an explanation for these observations.[138] When cells are rapidly deoxygenated the solubility is suddenly decreased to a low value. The resulting high supersaturation (the ratio of the total concentration to the solubility) causes a high rate of homogeneous nucleation, and the resulting gel contains a very large number of small polymer domains or randomly oriented polymers that could give the cell a granular appearance (Fig 3). In contrast, when deoxygenation is slow, the rate of homogeneous nucleation is reduced to the point that only one homogeneous nucleation event takes place in the cell, and a single polymer domain forms. If it were not for the limited amount of hemoglobin in the cell, this domain would grow to a much larger size than the cell. The cell membrane presumably restricts domain growth to one general direction, resulting in an elongated cell with approximately parallel polymers, the classic "sickle" form (Fig 3). At intermediate rates of deoxygenation, cells may contain a countable number of domains, where, for example, each domain could produce one of the projections of a so-called "holly-leaf" shape (Fig 3).

The appearance of a wide range of morphological forms at a fixed rate of deoxygenation might also be explained as resulting from different rates of polymerization. Remember that the solubility of hemoglobin S decreases very rapidly at high fractional saturations and much more slowly at low fractional saturations (Fig 2 b). Consequently at a fixed deoxygenation rate dense cells become much more supersaturated and consequently polymerize with much shorter delay times than the light cells. As a result dense cells would be expected to contain many more polymer domains and to have a lumpy, granular appearance, as opposed to a classic sickle shape. Cell morphology is therefore expected to be highly correlated with intracellular concentration and cell density. The results of morphological studies on cells polymerized at different rates[151] and on density fractionated cells are consistent with this explanation.[85] The observation of smooth discocytes containing polymer in time-resolved electron microscope studies may represent the initial phase in the formation of a granular form.[152]

GELATION IN VIVO AND VASO-OCCLUSION

We now turn to the question of obstruction of blood flow in the microvasculature resulting from intracellular gelation. Vaso-occlusion is believed to be the cause of pain crises and of the widespread organ damage that contributes substantially to the morbidity and mortality of the disease. Because of the enormous complexity of this problem, the discussion must, of necessity, become much more qualitative and speculative than that which has been presented up to now. We shall see that there are suprisingly little hard data on some of the most basic questions about vaso-occlusion. Nevertheless we believe that a critical examination of this problem is necessary at this point to clarify the important issues and to point to areas where research is most needed. We first discuss gelation and vaso-occulsion, and in the next section we consider the response of the circulatory system to this abnormality.

To gain some perspective on the problem it is instructive to consider the various types of events that have been postulated to occur as a red cell travels through the circulation of an SS patient. In describing these events we shall equate sickling with intracellular gelation. Figure 8 shows a schematic summary. Cells containing no polymerized hemoglobin in the arterial circulation may pass through the microcirculation and return to the lungs without sickling, they may sickle in the veins, or they may sickle in the capillaries. The probability for each of these events will be determined by the delay time for intracellular gelation relative to the appropriate transit time.[7] If it is thermodynamically impossible for gelation to take place (ie, the intracellular concentration is always lower than the solubility so that at equilibrium no polymer can form) or if the delay time at venous oxygen pressures is longer than about 15 seconds, then sickling will not occur. If the delay time is between about one and 15 seconds, then the cell will sickle in the veins, and, if it is less than about one second, the cell will sickle within the capillaries. For cells that sickle within the capillaries a number of possibilities exist, ranging from no effect on its transit time to transient occlusion of the capillary or a more permanent blockage that ultimately results in destruction of the cell. For some cells the intracellular hemoglobin S concentration may be so high that the solubility is exceeded even at arterial oxygen pressures. These cells will still contain polymerized hemoglobin after oxygenation in the lungs. Upon deoxygenation further gelation will occur rapidly and without a delay time because nucleation of polymers is already complete.[7,22,77,136,137] Such cells could become stuck in the arterioles or capillaries or could experience a normal transit time through the microcirculation in spite of the decreased deformability.

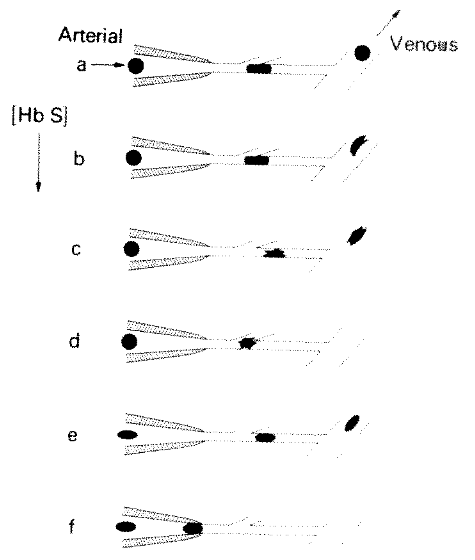

Fig 8. Possible events in the microcirculation of a patient with homozygous SS disease. A schematic of an arteriole, capillary, and venule is shown. In (a) a cell containing no polymer enters the capillary, deforms to squeeze through, and reaches the venule without polymerization occurring. In (b) the delay time is longer than the capillary transit time, but the cell sickles in the venule. In (c) the delay time is shorter than the capillary transit time, and the cell sickles within the capillary but escapes to the venule, while in (d) intracapillary sickling results in transient or permanent blockage. In (e) and (f), the cell, depicted as an irreversibly sickled cell, already contains polymerized hemoglobin in the arteriole and may pass through the capillary (e) or produce a transient or permanent occlusion (f).

Figure 8 points out one fundamental problem in describing the pathophysiology of sickle cell disease is to determine the relative probabilities for each of these events. These probabilities will depend on a number of factors, including the total intracellular hemoglobin concentration, the composition of the intracellular hemoglobin, the rate and extent of deoxygenation, and the various transit times involved. For unsickled cells entering the microcirculation, a long capillary transit time will increase the probability of the potentially vaso-occlusive events depicted in Fig 8 in two ways. First, it will permit increased oxygen extraction, which will shorten the delay time. Second, it will increase the probability that a cell with a given delay time will sickle within the capillary. For cells that either enter the microcirculation already sickled or become sickled in the microcirculation, there is a finite probability for occlusion of the small vessels. The duration of an occlusion may be sufficiently long to compromise the oxygen supply to the surrounding tissues and hence may alter the probabilities for sickling and consequent vaso-occlusion in nearby microvessels. This is a somewhat refined version of the "vicious cycle."[153] It is important to recognize that vaso-occlusion is a dynamic process in which the fraction of capillaries that are occluded depends on both the rates of occlusion and the rate of capillary reopening. Thus factors that influence the transit times and the duration of occlusions also play a critical role in the pathophysiology.[7]

With this brief heuristic description as a framework for subsequent discussion, we can now proceed to examine experimental results that help to establish the probabilities for the various events depicted in Fig 8. The most straightforward problem is the determination of the fraction of cells that are sickled in the arteries and the fraction that sickle as a result of deoxygenation in the microcirculation. Morphological examination of cells sampled from arterial blood suggests that the average fraction of sickled cells is about 10%.[78,154-156] This number is, unfortunately, only a rather crude estimate because it is possible that deformed cells such as granular discocytes have not been counted as sickled in some studies; moreover, some irreversibly sickled cells, which may frequently be a major contributor to this count,[156] may contain no polymer.[140] The values for reversibly sickled cells in different patients range from 1% to 16%, while total sickled cell counts range from 9% to 30%.[156] This variation presumably results from differences in the distribution of intracellular hemoglobin composition and concentration, as well as from differences in arterial oxygen saturation.

It would appear, then, that an average of about 90% of cells entering the peripheral circulation contain no polymer and hence would undergo gelation with a delay period if sufficiently deoxygenated. The morphological data suggest that about 20% of cells are sickled in the mixed venous return,[78,154-156] indicating that an additional 10% of cells have sickled as a result of passing through the microcirculation.* Any analysis based on studies of mixed arterial and venous blood is clearly somewhat oversimplified because oxygen extraction in the microcirculation of some tissues, such as in the coronary and hepatic circulations,[155] is considerably greater than average. As a result the cells in these organs will have much shorter delay times leading to a higher number of sickled cells in the veins.

These findings are consistent with existing information on in vitro delay times. Although the ideal in vitro experiment in which gelation and degelation are continuously monitored in individual red cells at physiologic rates of deoxygenation and oxygenation is not yet possible, the laser photolysis experiment[136,137] affords an informative preview of the results expected from such experiments. The *unsickling* curves obtained in these experiments (Fig 7) show that *at equilibrium* only about 5% of the cells contain polymerized hemoglobin S at an oxygen pressure of 85 torr, which is the average arterial value found in homozygous SS patients,[78] while over 90% of cells remain sickled at the average mixed venous pressure of 45 torr. In contrast, the *sickling* curves show that only about 5% of cells (overlapping significantly with the cells that were found to be sickled at 85 torr at equilibrium) are sickled after deoxygenation to venous oxygen pressures on physiologic time scales. These results indicate that the delay time is preventing more than 80% of cells from sickling in vivo in this homozygous SS patient. That is, for over 80% of cells gelation would occur if equilibrium were achieved, but the delay times are so long that these cells return to the lungs and are reoxygenated before any significant amount of polymer has formed. The fact that about 10% of cells already contain polymer in the arterial circulation does not substantially affect the fraction of sickled cells in the microcirculation, since if polymer were not present the delay times for the large majority of these cells would be less than the capillary transit time.† The enormous difference between the unsickling curve and the sickling curve in these experiments (Fig 7) graphically demonstrates the significance of the delay time for gelation in vivo and simultaneously shows that equilibrium data or data obtained in slow deoxygenation experiments are not at all representative of the in vivo situation in which the relevant time scale is seconds. Similar large differences are expected for oxygen binding and polymer fraction curves (Fig 2 e, 2 f and discussion below).

This analysis points to the critical need for obtaining much more data relevant to sickling in vivo. An accurate description would require direct measurements of the distribution of delay times at physiologic rates and extents of deoxygenation. It would also be desirable to have more precise data on the extent of sickling in arterial and venous samples using experimental methods that take into account the kinetics of sickling as well as the recently acquired information on the relation between cellular deformation and intracellular gelation.[136,137,140] Most of the data on morphological sickling were obtained before the gelation kinetics were described, and since then very little attention has been given to designing accurate morphological experiments on venous and arterial samples. Such experiments would require rapid fixation of cells and careful examination by scanning electron microscopy or high resolution optical microscopy. It would, of course, be preferable to develop rapid sampling techniques that could assess the extent of intracellular gelation, or at least the presence or absence of polymer, in individual cells from arterial and venous blood.

We next consider the question of occlusion of the microcirculation by sickled cells, which is clearly a central problem in understanding the pathogenesis. The results and calculations described above as well as data on red cell survival suggest that the densest cells are primarily responsible for occlusion of the microcirculation. These cells are predicted to have a much greater probability for the events in Fig 8 that could lead to vaso-occlusion. Because of the high intracellular hemoglobin S concentration, they have shorter delay times, or no delay times and therefore are more likely to sickle in the capillaries when deoxygenated.[6,7] In addition, if gelation occurs at any given oxygen pressure, the higher intracellular concentrations of polymerized hemoglobin (Fig 2 d) produces stiffer cells (ie, cells with lower static and dynamic deformabilities[140]). The half-life of dense cells (~ two days) is significantly shorter than that of randomly labeled cells from the same patient population (~ five days)[164] or the average half-life of cohort-labeled cells from a wider patient population (~ 17 days).[164-166] Experiments in which the density distribution of a population of labeled reticulocytes was followed over the cell life span also show that the dense cells are the last to appear in the labeled population.[164] These results show clearly that as cells age their density increases and that once they become dense they are removed from the circulation rather quickly.[164] The mechanism by which cells concentrate has been the subject of much recent work.[167] The major contribution appears to result from the loss of cell water associated with potassium loss, but there may also be some contribution from the loss of membrane surface area caused by the sickling-unsickling cycle. If it is assumed that all cells must become dense cells before they are removed from the circulation, then the fraction of dense cells is predicted to be equal to the ratio of the half-life of the dense cells to the mean half-life for new cells. The measured half-life of the dense cell fraction is roughly consistent with this prediction, since the densest 10% to 15% of the cell population has a half-life that is 0.1 to 0.2 times that of labeled reticulocytes.[164] Cells that have an abnormally low probability of sickling, such as low density F cells, are expected to have extremely long delay times even at venous saturations. Since these cells can only be sickled upon stasis or passage through tissues where deoxygenation is extreme, they will presumably concentrate much more slowly than cells having a higher probability of sickling. This protection of F cells results in a longer life span[1] and therefore an increased concentration of F cells in the fractions of intermediate density, which represent the oldest cells in the population, and a reduced concentration in the densest cell fraction.[87,164]

---

*The estimate of 10% additional sickling in the microcirculation is only a very approximate number. Differences in this number are observed for different venous returns of the same patient and for the same venous return in different patients, but the tissue-to-tissue variation is generally smaller than the differences observed between patients.[78,155,156] Since cells are deoxygenated in the microcirculation within one to two seconds, significant variations may result from additional sickling during the time required to sample the cells from the veins and to fix them with glutaraldehyde and possibly some additional unsickling for cells sampled from the arteries.[157,158]

†Shearing forces are known to decrease the delay time by breaking polymers, producing new ends, and thereby increasing the rate of nucleation.[121,139,159,160] In this discussion we have assumed that there is no significant effect of shear on the in vivo delay time. While no direct experimental information on this point exists, two considerations suggest that the effect of shear on intracellular polymerization in vivo will be small. First, cells flowing in small tubes concentrate in the low-shear region near the center of the tube, while the high shear regions near the walls are preferentially occupied by plasma.[161,162] The shear field to which cells are exposed is thus very much smaller than the average field in the microvessels. Second, the high internal viscosity of even unpolymerized cells makes coupling of the external shear field to the inside of the cell inefficient, as evidenced by the absence of tank-treading behavior in low viscosity media.[163]

Of the vaso-occlusive events depicted in Fig 8, it is only possible to make even a crude quantitative estimate for the probability of occlusion followed by *destruction* of the cell. Based on a mean cell lifetime of 17 days and a circulation time of 15 seconds, an "average" red cell makes about 100,000 trips through the microcirculation before being removed. If we use the fraction of sickled cells as an estimate of the fraction of dense cells (~20%), the above argument suggests that if dense cells were removed from the circulation only by vaso-occlusive events, they would be trapped and destroyed once in about 20,000 trips through the microcirculation. However, hemolysis data indicate that about 60% to 70% of sickle cells are destroyed in the reticuloendothelial system,[166] so the probability for destructive vaso-occlusion is reduced to about one in 60,000 trips. While this probability appears, at first glance, to be extremely low, it is large enough to result in the steady-state blockage of a significant fraction of the total number of capillaries, since there are approximately 10^{13} circulating red cells and only about 10^{10} capillaries.[168] The exact fraction blocked is highly dependent on the duration of the destructive blockade, which, by this estimate, occurs in the average capillary about once every hour. If, for example, each blocked vessel remains occluded for one hour, the fraction blocked is 50%, but this value is reduced to 2% if the vessel is blocked for only one minute. This result clearly suggests that factors that influence the duration of a capillary blockade could play a critical role in determining the extent to which tissue oxygen supply is compromised.

It has been very difficult to obtain quantitative information on the frequency of the other events depicted in Fig 8. Recently a series of studies using an excised rat mesocecum preparation has begun to provide some interesting results. This preparation permits control over the tissue oxygen pressure and the perfusing pressure, allowing vascular resistance (defined as the ratio of the arteriovenous pressure difference divided by the venous outflow) changes to be measured quantitatively in both denervated[85,86] and innervated vascular beds.[169] Alternatively, trapping of cells can be measured by first perfusing the innervated bed and subsequently washing out the trapped cells by increasing the perfusion pressure or denervating the prepared bed.[169] These experiments make two important points. The first is that at venous Po_2 the fraction of capillaries blocked at steady state in this preparation can be as large as 80%. The second is that the ability of cells to block the microcirculation is correlated with their density, a finding that is consistent with the description of Fig 8.

These investigations provide the best opportunity to simulate the events occurring in the microcirculation of SS patients. In addition to measuring vascular resistance and cell trapping, cinematographic observations of these preparations permit determination of the sites at which blockage occurs. The limited information obtained so far has not established the relative importance of precapillary and intracapillary sites as the principal sites of occlusion.[170-172] It would be important to extend studies of the microvasculature to use preparations that permit deoxygenation in the tissue[170] to more closely simulate the in vivo situation. It will also be important to use these preparations to determine the factors that affect both the frequency and duration of occlusions, since they are equally important in determining the steady-state fraction of blocked capillaries.

GELATION AND OXYGEN DELIVERY

An important aspect of the pathophysiology of sickle cell disease is to understand how the circulatory system maintains adequate oxygen delivery in the face of anemia and vascular obstruction. In other severe anemias, for example, those arising from blood loss or iron deficiency, there are two primary compensation mechanisms. One is an increased blood flow through the tissues resulting from an expansion of the muscled arterioles.[173,174] The increased blood flow from this decreased peripheral resistance increases filling of the right atrium, thereby increasing the cardiac output.[175] The second is an increase in intracellular 2,3-DPG concentration, which lowers the oxygen affinity and facilitates oxygen unloading in the tissues.[25] As a result there is an abnormally low venous oxygen saturation at or near a normal oxygen pressure.[173,174,176-178] The increased blood flow through the lungs may also result in a decreased oxygen pressure and saturation in arterial blood[173,176,179] from the decreased efficiency of gas exchange,[180] making oxygen delivery less efficient.

In sickle cell disease the abnormalities are somewhat different. The cardiac output is higher than in anemias of comparable severity,[78,173,176,181] the oxygen pressure and saturation of arterial blood are lower,[78,154-156,182,183] and the oxygen pressure and saturation of venous blood are higher.[78,154,156] This decrease in arteriovenous saturation difference, particularly when compared to other anemic states, means that there is significant impairment of oxygen unloading to the tissues.[78] These differences between sickle cell disease and other anemias presumably result from the intracellular gelation and vascular obstruction that are unique to sickle cell disease.

The very low oxygen affinity of polymerized hemoglobin S explains the lower arterial oxygen saturation in sickle cell disease, compared with other anemias, and even the lower arterial oxygen pressure. Infarctive damage to lung tissue of SS patients could also decrease the efficiency of oxygen loading in the lungs, but this does not appear to be a major factor because a comparable degree of arterial unsaturation is observed in children in whom there is no other evidence of impaired lung function.[184,185] We have estimated earlier that about 20% of cells entering the lungs contain substantial amounts of polymerized hemoglobin, which would be expected to decrease both the rate and extent of oxygen binding to the sickled cells in the alveoli. The few in vitro experiments support this contention.[152,157,158,186] Slow depolymerization of the sickled cells after they leave the lungs could also contribute to the lower arterial oxygen tension by scavenging oxygen from the plasma and from the cells that contain no polymer.

In considering oxygen unloading in the tissues, the absence of polymerized hemoglobin in most cells because of the long delay times is an important consideration. The traditional approach has been to ignore this fact and to utilize oxygen dissociation curves measured in vitro over periods of minutes or longer where intracellular gelation is much more extensive than in the in vivo situation. Use of the in vitro curve has led to the conclusion that the large right shift in the equilibrium or quasi-equilibrium dissociation curves substantially compensates for the anemia.[173,187,188] This conclusion is misleading, since oxygen binding to approximately 80% of the cells should be similar to that found for other states of comparable anemia. The calculation in Fig 2 e shows that the in vivo oxygen unloading curve is predicted to be significantly less right shifted than the in vitro equilibrium curve. This smaller right shift is consistent with the observation that the fractional saturation of venous blood from sickle cell patients has near normal values, while the oxygen pressure is higher than in normal blood by about 5 torr.[78]

Perhaps the most puzzling circulatory abnormality is an increase in cardiac output that is larger than is found in anemias of comparable severity. The absence of a significant increase in arterial blood pressure[189] requires that the vascular resistance be *decreased* in direct proportion to the increase in cardiac output.[78] While decreased vascular resistance may appear paradoxical in the presence of capillary blockage,‡ this finding can be rationalized by the fact that the bulk of the peripheral resistance arises from the muscled arterioles and not the capillaries.[192] In severely anemic states the arterioles open to increase blood flow through the tissues, thereby compensating for the low hematocrit.[173,174] A similar response also appears to be the primary mechanism of compensation for the reduced hematocrit in SS disease, but the peripheral resistance is decreased to a significantly greater extent than in other anemias of comparable severity.[78,173] The opening of the muscled arterioles must therefore increase the fraction of capillaries in the tissue bed that are perfused to above normal, even in the presence of blockage, if there is sufficient capillary reserve.

In addition to increasing the number of perfused capillaries, there is evidence that opening of the muscled arterioles increases the pressure drop across the capillaries, thereby increasing the rate at which red cells traverse the capillaries.[192-194] A recent study in which laser Doppler velocimetry was used to measure capillary flow in the forearm skin of SS patients showed that the average rate of *red cell* flow was close to normal.[195] This result implies that the ~40% decrease in hematocrit is almost exactly compensated by a combination of an increase in the number of perfused capillaries and an increase in capillary flow rate. By decreasing the time available for the equilibration of the red cell with the oxygen tension of the capillary wall, an increased capillary flow rate would be expected to decrease oxygen unloading. In spite of this effect a decreased capillary transit time could benefit the patient by decreasing the rate of capillary blockage. The decreased transit time would not only increase the delay time by increasing the final fractional saturation of hemoglobin but it would also decrease the time during which a cell is at risk from sickling within the microcirculation. Such a mechanism provides an attractive explanation for the decreased arteriovenous oxygen saturation difference in SS patients. A frequently invoked explanation for the low arteriovenous saturation difference is shunting through large vessels.[154]

---

‡There is no direct measurement of the fraction of occluded capillaries in any tissue in sickle cell disease. However, a tentative estimate for muscle can be extracted from data on the exercise tolerance of sickle cell patients.[190] In these studies patients were subjected to increasing work loads, and the lactic acid level in the blood was monitored. The work load at which lactate began to increase is defined as the anaerobic threshold. An extension of the Krough model for oxygen delivery to tissues predicts that the work output at this point is nearly directly proportional to the density of perfused capillaries.[191] If it is assumed that the muscle is maximally perfused and that capillary densities in the muscle of SS patients are normal, then the fraction of blocked capillaries can be estimated from the anaerobic threshold to be about 0.4. This fraction decreases to about 0.1 to 0.2 when the fraction of SS cells is decreased to about 50% by exchange transfusion.[190]

While this mechanism might account for the unexpectedly high venous saturation in specific tissues, it cannot explain the fact that similar results are found for vessels such as the femoral vein.[78] The femoral vein primarily drains muscle beds in which there is anatomic evidence that significant shunting is impossible.[196]

Finally, we should point out that there has been only one attempt to quantitatively evaluate the response of the complete circulatory system to the altered properties of SS blood.[197] This study used an established model for microcirculatory control[198] to calculate the changes in peripheral resistance blood flow, and capillary oxygenation.[197] This model incorporates approximate but realistic descriptions of oxygen supply and consumption in the tissues as well as local feedback control of both the arteriolar resistance and capillary density to regulate the tissue oxygen pressure. When anemia is simulated by reducing the hematocrit, the model predicts a compensatory decrease in peripheral resistance and increased blood flow. If, however, the quasi-equilibrium increase in viscosity and reduced equilibrium affinity of SS blood are also introduced, the model predicts a capillary resistance that is about 1.4 times normal and blood flow that is about 80% of normal. The calculated effects are in striking contrast to the observed *decrease* in peripheral resistance and *increase* in blood flow.[78,181] The discrepancy presumably results in part from the incorrect assumption of equilibrium oxygen unloading and viscosity changes made in carrying out these calculations. If the kinetics of intracellular gelation were to be incorporated into this model (Fig 2 e), the predicted effects would be closer to the observed.

VARIATIONS IN CLINICAL SEVERITY

It is now widely recognized that there are large differences in clinical severity among patients with homozygous SS disease, some patients having only the mild symptoms associated with a chronic hemolytic anemia, others suffering from repeated painful episodes and severe organ damage.[24,25,199,200] The reasons for this broad spectrum of clinical manifestations are not at all clear, and it is one of the major areas of current research. To discuss the role of gelation in producing differences in clinical severity among homozygous SS patients, it is useful to briefly summarize the most important results of the preceding discussion.

The picture that emerges is a dynamic one in which a balance between the rate of obstruction and reopening of capillaries results in a steady state in which a certain fraction of capillaries is blocked in each tissue. This balance may be very delicate, with small changes in either the rate of obstruction or reopening capable of significantly altering the fraction of occluded capillaries. Any increase in this fraction, particularly in tissues with inadequate capillary reserve, could result in irreversible hypoxic damage and may be the cause of pain crises. While almost nothing is known about the opening of occluded capillaries, we are beginning to understand the mechanisms that control the rate of capillary obstruction. This rate must depend, at least in part, on the fraction of sickled cells in the microcirculation, which is determined by the times required for intracellular gelation relative to the transit times.[6,7] Factors that favor gelation can increase the steady state number of obstructed capillaries by decreasing the delay time, thereby increasing the fraction of cells that sickle within the microcirculation and the rate of obstruction. An increased extent of polymerization in a sickled cell could also increase the probability of an occlusion because of the decrease in deformability.[140] Because the delay time is so much more sensitive to changes in physiologic variables than the extent of polymerization (compare, eg, Figs 2 d and 3), it is most probably the dominant factor in determining changes in the rate of capillary obstruction. Simultaneous small changes in a number of physiologic variables could result in a sufficient change in the distribution of delay times to produce the fluctuation in the fraction of blocked capillaries that precipitates a pain crisis. In this way the sensitivity of the delay time could account for the episodic nature of crises.

Another mechanism for increasing the rate of obstruction is to increase the transit time in the microcirculation, which increases the probability of sickling. In this way factors that slow down cells can also affect the rate of obstruction. The only such factor that has been identified so far is the adherence of cells to the vascular endothelium.[201-204] In addition to capillary blockage, other events influence these probabilities by altering the characteristics of the cell population. For example, cells that normally would return to the lungs may sickle in the venous return, particularly in tissues in which the residence times in the veins are long, resulting in an increase in intracellular concentration and therefore a decreased delay time in subsequent trips through the microcirculation.

This picture immediately raises the question of how much of the variation in clinical severity in homozygous SS disease can be explained by variations in intracellular gelation and how much must be attributed to variations in circulatory dynamics. Under the category of intracellular gelation are included the effects of intracellular hemoglobin concentration and composition, arising either from genetic variations or from cell aging. To begin, let us consider the relation between gelation times and clinical severity among the various sickling disorders, where there are easily measurable differences in both gelation and standard hematologic parameters. Figure 9 shows the effect of hemoglobins A, C, and F on the delay time and a comparison of the distribution of delay times at zero saturation for the three most common syndromes: homozygous SS disease, SC disease, and sickle trait. SC disease is generally a much milder sickling disorder than is SS disease, while sickle trait is totally benign.[24,25] The delay times for SC cells are considerably longer than those for SS cells, indicating that many fewer cells sickle in vivo. For sickle trait cells the delay times even at zero saturation are all longer than about one second, indicating that even under totally anoxic conditions cells would escape the microcirculation before polymerization has begun. With the possible exceptions of the hypertonic renal medulla, it would appear that sickle trait cells never sickle in vivo, explaining the lack of any clinical manifestations.

The reasons for the increased sickling of SC cells compared to sickle trait cells are quite interesting. Little or no difference is observed in the gelling properties of hemoglobin S + C mixtures and S + A mixtures. A careful comparison has shown that there are no significant differences in either

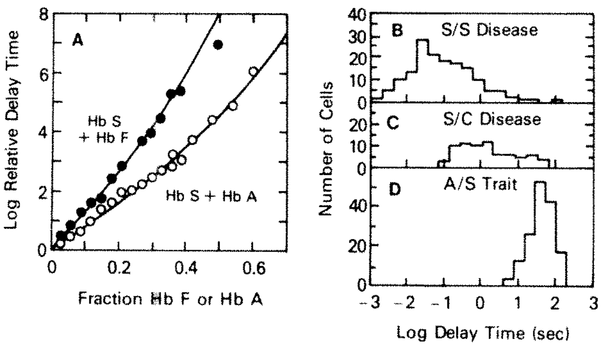

Fig 9. Effect of non-S hemoglobins on gelation delay times in solutions and cells. (A) Logarithm of the ratio of the delay time of the mixture to the delay time of pure deoxyhemoglobin S at the same total hemoglobin concentration.[57] The effect of hemoglobin C on the delay time is identical to that of hemoglobin A.[62] (B, C, D) Distribution of delay times at zero saturation for cells from a patient with homozygous SS disease (B), hemoglobin SC disease (C), and sickle trait (D) at 37°C. The data in (B) and (C) are taken from Coletta et al,[135] while the data in (D) is from Zarkowsky and Hochmuth[143] after using the temperature dependence of the median delay time to correct the data to 37°C.

the delay times[62] or solubilities.[62,63] The principal reason for the increased sickling of SC cells is that they contain a higher hemoglobin S concentration than sickle trait cells. This increase results from two effects.[62] First, there is a greater fraction of hemoglobin S in SC cells (50/50 S/C) than in sickle trait cells (40/60 to 30/70 S/A). The reduction in the fraction of hemoglobin S in sickle trait cells is caused by a decreased rate of association of α chains to β^S chains relative to β^A chains during the tetramer assembly process.[205,206] When the concentration of α chains is reduced because of coexisting α thalassemia, this competition is enhanced and a disproportionately larger fraction of β^A-containing tetramers are formed. Second, the total intracellular hemoglobin concentration is higher in SC cells.[62,84] Since reticulocytes have nearly the same density distribution as the average cell population, the red cells must emerge from the marrow more concentrated. The reasons for this are not yet completely understood, but it has been suggested that the binding of hemoglobin C to the red cell membrane induces a potassium and water efflux.[207]

Hemoglobin F also has a marked effect on gelation. This is clinically most evident in the uncommon double heterozygous condition of hemoglobin S with pancellular hereditary persistence of fetal hemoglobin, which may be asymptomatic. In this condition hemoglobin F is more evenly distributed, and most cells contain a substantial amount of hemoglobin F (up to 35%).[24] This mixture has gelling properties in vitro that are similar to the 40/60 Hb S + A mixture found in sickle cell trait (Fig 9)[37,57] and would therefore be predicted to have a very mild or asymptomatic clinical course. In homozygous SS disease there is a variable increase in hemoglobin F that results from two factors: an increased production of F reticulocytes and preferential survival of F cells.[81] At hemoglobin F levels above 20%, corresponding to about 60% F cells, there may be some amelioration of the disease, but below 20% there appears to be no significant effect.[201,208]

Because of the tremendous sensitivity of the delay time to the total hemoglobin concentration, it has been suggested that the clinical severity of homozygous SS disease may be improved by a small dilution of the intracellular hemoglobin.[6,7] The increase in the delay time resulting from a decrease in the intracellular concentration would allow more cells to escape the microcirculation before gelation has begun.[6,7] To estimate the effect of concentration on the delay time we use a 15th power inverse concentration dependence, since this is the concentration dependence found for delay times of about one second (Fig 3). The decrease in MCHC from 32 g/dL to 30 g/dL associated with the coexistence of α thalassemia, in which two of the four α genes are deleted $(-\alpha/-\alpha)$,[239] produces an almost three-fold increase in the delay time for the "average cell." The result is increased red cell survival[87,210] and an indication of fewer episodes of the acute chest syndrome and leg ulceration.[211,212] Also, in SS disease there may be an increased frequency of the α gene deletion with age, suggesting that a decreased total intracellular hemoglobin concentration is associated with a longer life expectancy.[213] In HbS-β^0-thalassemia there is a similar decrease in MCHC, and the clinical course relative to SS disease is "milder in many features."[24]

Thus far we have seen that for genetically different sickling disorders there is a good correlation between intracellular gelation in vitro, for solutions having compositions of the average cell, and disease severity for the average patient.§ To investigate the role of clinical diversity one would ideally want to know at least the distribution of intracellular delay times for patients from a clinically well-characterized population. No such data are yet available. An efficient but limited method of examining distributions of intracellular gelation is to measure density distributions, since the density is proportional to the total intracellular hemoglobin concentrations. Differences in intracellular solvent conditions of pH, 2,3-DPG concentration, etc, are expected to have a much smaller effect on gelation than differences in intracellular hemoglobin concentrations. Consequently the distribution is expected to reflect the distribution of intracellular delay times, except for the effect of F cells.

The only study carried out so far is one in which cell density distributions were compared with the incidence of painful crisis.[214] No correlation was found between the fraction of cells in the highest density range and crisis frequency. This result was interpreted as evidence that the greater probability of intravascular sickling is not the principal cause of increased crisis frequency, but that variations in the anatomy and dynamic properties of the microcirculation are responsible for differences among patients. As pointed out earlier, one factor that could be important in determining transit times in the microcirculation is adherence to the vascular endothelium. A strong correlation has in fact been found between overall clinical severity and the tendency of the red cells to adhere to vascular endothelium in in vitro experiments.[201-203] The severity score used in this study included evidence for organ damage resulting from microvascular occlusions as well as the frequency of pain crises. In this same study there was no correlation between severity and hemoglobin F levels or irreversibly sickled cells, which are known to correlate with the fraction of dense cells.[82]

---

§Correlations between gelation and both overall clinical severity and degree of anemia have also been obtained using the in vitro fraction polymerized *at equilibrium* as a measure of gelation in vivo.[209] Although the equilibrium fraction polymerized in vitro is not relevant to the in vivo situation as discussed earlier, these correlations give a very similar result[209] because of the close correlation between the kinetic and equilibrium properties of gelation.[36]

THE PROBLEM OF INHIBITING GELATION IN PATIENTS

The strong correlation between gelation and severity for the "average" patient with the various sickling disorders clearly indicates that inhibition of gelation should result in amelioration of the disease. The data on hemoglobin mixtures shows that it will not be necessary to completely inhibit gelation (ie, increase the solubility such that it equals or exceeds the total intracellular hemoglobin concentrations at all oxygen pressures) but that a therapeutic effect should result from sufficiently increasing the delay time to allow more cells to escape the microcirculation and be reoxygenated in the lungs before gelation has begun.[6,7,57,98] In this way there should be a reduction in the rate of production of dehydrated, rapidly polymerizing cells, which have been generally assumed to be the subpopulation of cells most responsible for initiating vaso-occlusion.[5] To give this concept a quantitative basis we may ask: how much must gelation be inhibited to obtain a specified therapeutic effect in patients? An approximate answer to this question can be obtained from the correlation between in vitro delay times or solubilities in solutions of deoxyhemoglobin mixtures having the compositions found in various sickling disorders and their "average" clinical course.[57]

The data for this comparison are found in Fig 9, and Table 1 shows the increase in delay time and solubility relative to pure deoxyhemoglobin S for solutions having the hemoglobin composition found in sickle-β^+-thalassemia, sickle cell disease with hereditary persistence of fetal hemoglobin, and sickle trait. The results in Table 1 establish a set of criteria for obtaining a specified therapeutic effect. They suggest that the threshold for obtaining a therapeutic effect in SS disease would result from a method that produces an increase in the in vitro delay time of about a factor of 100 (corresponding to a solubility ratio of about 1.2), which is the increase found for solutions having the hemoglobin composition of sickle-β^+-thalassemia; an increase of about 10^3 to 10^5 (solubility ratio of about 1.3) should produce a major therapeutic effect; and a 10^6 to 10^8-fold increase in the in vitro delay time (solubility ratio of about 1.5 to 1.6), found for solutions with the composition of sickle trait cells, is predicted to result in a "cure."

Table 1. Clinical Course, Gelation Delay Time and Requirements for Therapy

Disorder	S/β^+-Thalassemia	S/HPHF	A/S Trait
Clinical course relative to S/S disease	Less severe	Much less severe	No disease
Red cell composition*			
% Hb A	20-30	0	60-75
% Hb F	0	20-35	0
% Hb S	80-70	80-65	40-25
Log delay-time ratio†	1.5-2.5	2.5-5.0	6.0-8.0
Solubility ratio‡	1.1-1.2	1.2-1.35	1.45-1.65
Therapy requirements			
Percent saturation of inhibitory site§	20-40	40-55	≥65
Decrease in intracellular concentration (g/dL)‖	3-5	5-9	≥11

*The data are from Serjeant.[24] For S/β^+-thalassemia this is the composition of the non-F cells.

†This is the ratio of the delay time for the mixture to the delay time for pure deoxyhemoglobin S at the same total hemoglobin concentration and is obtained from the data in Fig 9. These ratios are for subphysiologic concentrations using the temperature-jump technique for measuring delay times. For physiologic concentrations where the dependence of the delay time on supersaturation is smaller, these ratios are expected to be smaller, as is found with intact cells (see Fig 9b to d).

‡This is the ratio of the solubility for the mixture to the solubility for pure deoxyhemoglobin S in the limit of no polymerized hemoglobin (from Eaton and Hofrichter[26]).

§This is the fractional saturation of an ideal inhibitory site, ie, one that completely prevents polymerization, required to produce the delay time increase for pure deoxyhemoglobin S.

‖This is the required decrease in intracellular concentration, assuming an intracellular hemoglobin S concentration of 34 g/dL in the cells entering the circulation in S/S disease.

Adapted from Sunshine et al.[57]

With these estimates we can examine the potential utility of the various strategies that have been proposed to inhibit gelation in patients. Four different approaches have been explored or considered in some detail: (1) blocking intermolecular contact formation in the polymer, (2) raising the oxygen affinity, (3) decreasing the total intracellular hemoglobin concentration, and (4) promoting fetal hemoglobin production. The oldest idea is to develop a competitive or covalent inhibitor that would bind stereospecifically to hemoglobin S and interfere with polymer formation. Two general types of mechanisms have been considered. In one the "drug" acts directly by binding to an intermolecular contact site in the polymer, thereby competitively inhibiting polymerization. In the other the "drug" inhibits polymerization indirectly by changing the conformation at the intermolecular contact site so that it no longer "fits" into the polymer. The direct approach to inhibiting gelation poses a number of problems. Unlike an enzyme, where a substrate analogue can be a powerful inhibitor of catalysis by binding to the active site, none of the known intermolecular contact sites provide such a target. There are no clefts, grooves, or other obvious structural features that can be used to design molecules with complementary structures that might bind to hemoglobin S with high specificity. Examination of the intermolecular contacts also gives no real clues. This result might have been anticipated because the interactions between molecules in the polymer are weak. One approach would be to determine the structure of hemoglobin-antibody complexes in which polymer contacts are the antigenic determinant. Since hapten-antibody interactions are generally much stronger, the antibody-binding site would be expected to have the structural features of a very effective inhibitor and hence could serve as a model for the ambitious organic chemist attempting to construct molecules that cover the contact sites.

A natural target on the hemoglobin molecule for attack by the indirect mechanism is the pocket between the β subunits, which constitutes a specific, relatively high-affinity binding site for 2,3-DPG. For example, bifunctional aspirin derivatives have been described that crosslink the β subunits by covalently binding to opposite β82 lysines.[215] Analysis of the three-dimensional structure of the complex by x-ray crystallography shows that this modification causes a shift in residues of the F-helix that are part of the acceptor site for the β6 contact region, explaining the very large increase in solubility (solubility ratios up 1.5).[19] Although these particular inhibitors may not turn out to be therapeutically useful, this and other recent studies[20,21] demonstrate the power and feasibility of using x-ray crystallography to understand the mechanism of action of inhibitors and to design more effective ones. Most studies of inhibitors of gelation have not taken such a "rational" approach. Nevertheless a number of effective inhibitors have been found, although none has been developed to the point of being a serious candidate for use in patients.[25,216-220]

A second, more speculative strategy for inhibiting gelation is to increase oxygen affinity by shifting the allosteric equilibrium toward the R structure. At any given oxygen pressure there will be a lower concentration of molecules in the T quaternary structure and therefore a decreased tendency to polymerize. Calculations based on the effect of saturation on gelation suggest that therapeutically useful effects might result, although homeostatic responses that maintain oxygen delivery could buffer the inhibitory effect.[57] One interesting way of shifting the allosteric equilibrium toward R and one that would require much lower doses of a drug than directly attacking the hemoglobin molecule would be to inhibit 2,3-DPG synthesis.[57] An additional beneficial effect would result from the fact that 2,3-DPG promotes gelation of T-state molecules.[39,42] It will be important to evaluate the effect of an increase in oxygen affinity in some detail because many inhibitors of deoxyhemoglobin S gelation also increase oxygen affinity.

The third strategy is to decrease the intracellular hemoglobin concentration, an idea directly generated from the kinetic studies.[6,7] This approach takes advantage of the enormous concentration dependence of the delay time. There are two obvious ways that could, in principle, be used to decrease the total intracellular hemoglobin concentration. One is to permanently increase the red cell volume, and the other is to reduce hemoglobin biosynthesis without a decrease in red cell volume, for example by slowly introducing iron deficiency.[7] There are some clinical data to suggest that concomitant iron deficiency is in fact beneficial.[221] The idea of swelling red cells has been tested in a preliminary way. A combination of sodium restriction, high fluid intake, and the use of an antidiuretic reduced the serum sodium to 120 to 125 mg/dL, which resulted in a 2 to 3 g/dL decrease in the MCHC.[9,222] Both the frequency and duration of painful crises appeared to be reduced. Although this study was quite limited, involving only three patients who served as their own controls, it suggests that small reductions in intracellular hemoglobin concentration may indeed have a therapeutic effect, as predicted from the in vitro gelation studies.[7] Another approach to swelling red cells in patients has been to alter the ion transport properties of the red cell membranes so as to affect a net water influx. Several agents have been described.[8,10-12,223,224] Of these the most extensively studied is ceteidil,[8,10,223,225] which may be effective in directly retarding the dehydration that produces the rapidly polymerizing dense cells as a result of sickling-unsickling cycles.[223] In a placebo-controlled, double blind study ceteidil had some effect in reducing the severity and duration of pain crises,[226] but there is yet no information on its effectiveness in decreasing crisis frequency or organ damage.

The fourth strategy for inhibiting gelation in patients is to stimulate the production of γ globin. As discussed earlier, the inhibitory effect results from the inability of the $\alpha_2\gamma_2$ or $\alpha_2\gamma\beta^S$ tetramers to copolymerize with $\alpha_2\beta^S_2$.[37] If γ chains are exchanged for β^S chains in all cells, then some therapeutic effect is expected with hemoglobin F levels of about 10% to 15% (Fig 9 and Table 1). If hemoglobin F is heterogeneously distributed, clinical data from Saudi Arabians, where sickle cell disease is milder, suggest that amelioration would result if the percentage of F reticulocytes exceeds 20%, which results in a steady-state level of about 60% F cells and 20% hemoglobin F.[227] Data on American blacks suggest that at hemoglobin F levels above 10% there is a decreased probability of major organ failure, while the threshold for a decrease in crisis frequency is about 20%.[208] Although the molecular mechanism is not at all well understood, significant stimulation of F reticulocyte production has been achieved in SS patients with two drugs: 5-azacytidine[3,4,228] and hydroxyurea.[5,229,230] With 5-azacytidine hemoglobin F levels of 12% and 20% were achieved in two patients treated for more than 100 days, and there was a concomitant decrease in pain crises.[228]

The preceding analysis indicates that there is cause for optimism, as there are several totally independent and viable approaches to the therapy of sickle cell disease. Too frequently a single approach has been criticized as not being useful because by itself it does not produce a dramatic effect in patients. There is, of course, no reason why a specific treatment for sickle cell disease could not consist of the use of several drugs simultaneously, each inhibiting gelation by a different mechanism and at nontoxic doses that would produce only a small effect if given alone.

ACKNOWLEDGMENT

We thank H. Franklin Bunn for many helpful discussions and criticisms.

A Glycoprotein Inhibitor of In Vitro Granulopoiesis Associated With AIDS

By Ira Z. Leiderman, Michael L. Greenberg, Bernard R. Adelsberg, and Frederick P. Siegal

Patients infected with the human immunodeficiency virus (HIV) often present with neutropenia. To elucidate the mechanism(s) of this HIV-related neutropenia, we assessed the proliferative capacity of the granulocyte-macrophage progenitor cell (CFU-GM) from the bone marrow (BM) of 78 patients within the AIDS spectrum manifesting symptoms or signs related to HIV infection. Of these, 70 had a significant deficit in the growth of this committed progenitor when compared with normal controls ($P < .01$). Further analysis revealed that the nucleated bone marrow cells from AIDS and AIDS-related complex (ARC) patients inhibited the growth of CFU-GMs from normal individuals when cocultured in agar ($P < .001$). Control CFU-GMs were also inhibited when they were cultured over feeder layers containing patients' BM cells ($P < .001$). Conditioned media obtained from the liquid culture of patients' BM cells did not inhibit normal control CFU-GM growth to a degree different from that of the cells themselves ($P > .4$). Analysis of these conditioned media by polyacrylamide gel electrophoresis (PAGE) revealed a unique glycoprotein (gp) with a mol wt of 84 kd. Further studies revealed that this gp possessed the inhibitory activity. These data suggest that this gp may be an important factor in HIV-related neutropenia. The presence of gp84 was independent of drugs administered to the patients.

LEUKOPENIA is frequently associated with human immunodeficiency virus (HIV) infection. Although lymphopenia, primarily due to a decrease in the absolute number of the T helper/inducer ($CD4^+$) subpopulation, has been emphasized in the literature,[1-3] neutropenia is seen in ~40% of patients who develop symptoms of HIV infection.[4,5] In addition, these patients apparently have a greater than normal tendency to become neutropenic after exposure to trimethoprim-sulfamethoxazole, an antimicrobial drug combination known to cause transient neutropenia in other patients.[6,7] The depletion of the helper/inducer T cell population has been attributed to cellular infection with HIV.[8] The CD4 molecule has been identified as a receptor for the virus, and its subsequent cytolytic activity depletes that cell population.[9-12] This mechanism has also been hypothesized for the depletion of $CD4^+$ monocytes.[13] Because the CD4 molecule has not been demonstrated on neutrophils, such a mechanism would be unlikely for the observed neutropenia.

To determine if the HIV-related neutropenia has a similar decrease in the growth of CFU-GMs, we cultured bone marrow (BM) cells from 78 patients within the AIDS spectrum manifesting symptoms or signs related to HIV infection for the preferential growth of this progenitor cell. These patients had decreased proliferation of their CFU-GMs, and their BM cells inhibited normal control CFU-GMs. Further studies revealed that a glycoprotein (gp) inhibitor of normal CFU-GM growth is recovered from the supernatants of liquid cultures of BM cells from HIV-infected individuals.

MATERIALS AND METHODS

Subjects. Fifty-three patients met the Centers for Disease Control's (CDC) case definition for AIDS[14]: 38 homosexual males, 13 intravenous (IV) drug abusers (IVDA) (9 males, 4 females), 1 male hemophiliac, and 1 female sexual contact of an IVDA. Twenty patients defined as having AIDS-related complex (ARC) had: (a) A decreased ratio (≤ 1.0) of helper/suppressor ($CD4^+/CD8^+$) T lymphocytes; (b) decreased in vitro lymphocyte blastogenic response to mitogens (phytohemagglutinin, PHA, concanavalin-A, and pokeweed mitogen, PWM); and (c) at least one of the following symptoms—fever of undetermined origin, nocturnal diaphoresis, lymphadenopathy, wasting, diarrhea, leukopenia, or oral candidiasis (12 homosexual males, 4 male and 4 female IVDA). Five homosexual males were classified as having persistent generalized lymphadenopathy (PGL); these patients also had a decreased ratio (≤ 1.0) of helper/suppressor T lymphocytes and lymphadenopathy at ≥ 2 extrainguinal sites but no other AIDS-defining symptoms.

Twenty-five healthy male and female medical personnel who denied any risk for developing AIDS were studied as normal controls. Informed, written consent was obtained from all subjects, and the project was approved by the institutional review board of the Mount Sinai School of Medicine (CUNY).

All subjects were screened for antibodies to HIV by an enzyme-immunoassay (lymphadenopathy-associated virus, LAV-EIA; Genetic Systems, Seattle). All subjects except the controls were repeatedly reactive in this assay, which has been shown to correlate completely with Western blot positivity and radioimmunoprecipitation with ^{35}S-cysteine–labeled HIV.[15]

Bone marrow and blood collection. BM was aspirated from the posterior iliac crest into a sterile plastic syringe containing 50 U preservative-free heparin (Weddel Pharmaceuticals, London) diluted in 1.0 mL McCoy's 5a tissue culture medium (GIBCO, Grand Island, NY). Peripheral blood (PB) for CFU-GM cultures was similarly collected.

Serum preparation. Venous blood samples collected into sterile evacuated tubes (Vacutainer, Becton Dickinson, Rutherford, NJ)

were allowed to clot at 4°C. The samples were centrifuged at 2,000 g for 10 minutes at 4°C, and the serum was collected and frozen at −70°C until used.

Cell separation. The anticoagulated BM was transferred from the syringe to a sterile polystyrene centrifuge tube (Corning, Corning, NY) and centrifuged at 250 g for 10 minutes at ambient temperature (22 ± 2°C). The buffy coat was aspirated and diluted with 2.5 mL McCoy's 5a medium. A nucleated cell count was performed manually, and the cell suspension was diluted to the appropriate concentration with McCoy's 5a.

Anticoagulated PB was transferred to a sterile disposable centrifuge tube (Corning) and diluted with an equal volume of sterile Hank's balanced salt solution (HBSS, GIBCO). Ten milliliters of a Ficoll-Hypaque solution (sp gr = 1.077) (LSM, Litton Bionetics, Kensington, MD) was layered under 40 mL diluted blood. The gradient was centrifuged at 250 g for 20 minutes at 4°C. The mononuclear cells (PB-MNCs) were aspirated from the Ficoll-Hypaque/plasma interface and washed twice with HBSS and were then diluted with 2.5 mL McCoy's 5a to the appropriate concentration.

Granulocyte-macrophage progenitor cell culture. A short-term, semisolid culture was used, similar to the system originally described by Pike and Robinson.[16] Cells in McCoy's 5a were cultured in a final concentration of 10% heat-inactivated fetal bovine serum (FBS, GIBCO), 10% giant cell tumor-conditioned medium (GCT-CM; GIBCO) as a source of colony-stimulating factor (CSF),[17] and 2 mmol/L L-glutamine and 1% antibiotic solution (100X PSF; Gibco). Warm bacto agar (Difco, Detroit) was added to a final concentration of 0.3%, and the suspension was well mixed. Then, 1.0 mL was dispensed into each of four 35 × 10-mm tissue culture dishes (Corning) and allowed to solidify. Final cell concentrations were 0.2×10^6/mL for BM cells and 1.0×10^6/mL for PB-MNCs. The cultures were incubated in an atmosphere of 5.0% CO_2/95% air at 37°C for 10 days. Colonies were scored as ≥40 cells/aggregate. All cultures were scored in triplicate on day 10. These final concentrations of BM nucleated cells and PB-MNCs were chosen because they produced approximately the same CFU-GM growth in healthy controls.[18]

Conditioned medium. Nucleated BM cells from patients and controls were prepared as described above. The nucleated cells were diluted to a concentration of 1.0×10^6/mL in McCoy's 5a supplemented with 20% heat-inactivated FBS. The cell suspension was dispensed into 25 cm^2 or 75 cm^2 tissue culture flasks (Corning), depending on the final volume. The cells were cultured in an atmosphere of 5% CO_2/95% air at 37°C for 7 days. The CM was harvested by double centrifugation to remove all cells. The cell-free CM was frozen at −20°C until used.

Feeder layers. Feeder layers (FLs) were prepared from BM cells or CM. The cells or CM was diluted in McCoy's 5a and supplemented with a final concentration of 20% heat-inactivated FBS, 2 mmol/L L-glutamine, and 1.0% antibiotic solution (100X PSF). Warm bacto agar was added to a final concentration of 0.5%. After thorough mixing, 1.0 mL of suspension was dispensed into 35 × 10-mm tissue culture dishes and allowed to solidify. FLs were overlayered with normal target cells in 0.3% agar as described above. The amount of CM, or CM precipitate or PAGE eluate (below), used in these cultures was the amount calculated to be produced by 0.2×10^6 BM cells.

Ammonium sulfate precipitation. CM was precipitated with saturated ammonium sulfate, which was added dropwise to an equal volume of CM with continuous stirring at 4°C. The stirring was continued for 2 hours. The CM/salt solution was then allowed to sit undisturbed overnight at 4°C. The precipitate was then pelleted by centrifugation at 15,000 g for 20 minutes at 4°C. The supernatant was saved, and the pelleted precipitate was resuspended in McCoy's 5a to a volume equal to the starting volume of the CM. Both the resuspended precipitate and the supernatant were dialyzed against 0.015 mol/L phosphate-buffered saline (PBS) at 4°C. Three buffer changes were made over 48 hours of dialysis. The dialyzed material was then removed and stored at −20°C until used.

PAGE. Ammonium sulfate precipitates of the CM were diluted 1:5 with sample buffer pH 6.8 (0.5 mol/L Tris-Cl, 1.25% glycerol, 0.05% bromophenol blue) and then run on 7.5% native polyacrylamide gels (PAGE); mol wt was determined in 7.5% gels containing 1% sodium dodecyl sulfate (SDS).[19] All gels were run at a constant current as a discontinuous system with the 7.5% running gel at pH 8.8, the 3% stacking gel at pH 6.8, and the Tris-glycine running buffer at pH 8.8. Proteins running into the gel were visualized by silver staining.[20] Glycoprotein (gp) bands were visualized by periodic acid-Schiff (PAS) staining.

Elution of proteins from PAGE. Proteins were eluted from the gel slices in an ISCO sample concentrator (Model 1750, ISCO, Lincoln, NB). In brief, lanes containing CM from both patients and controls were cut from the gels, and the individual lanes were sectioned. The gel sections were placed in individual sample cups to which 10 mL Tris-glycine buffer (pH 8.8) was added. Elution of the proteins was achieved at 3 W constant power for 2 hours. At that time, the protein/buffer solution was removed and dialyzed as described above. After dialysis, the protein concentration was determined by the method of Bradford.[21] This dilute protein solution was concentrated by centrifugation through a Centricon-10 microconcentrator (Amicon, Danvers, MA), and the final protein concentration was redetermined. Inhibitory activity was assayed by adding the concentrated eluate to the FL in place of the CM.

Western blot. The Western blot technique was adapted from the EIA described by Tsang and colleagues.[22] Antigen is run into a native or SDS-PAGE. A nitrocellulose membrane (BA-85; Shleicher and Schuell, Keene, NH) is placed over the gel, and the gel/nitrocellulose is sandwiched between two plastic pads. The sandwich is then immersed into cold Tris-glycine/methanol buffer and electrophoresed with constant voltage for 12 to 14 hours at 4°C. The nitrocellulose membrane is then incubated with the first antibody, rewashed, and then reincubated with a horseradish peroxidase-conjugated second antibody. Diaminobenzidine is then added, and any positive bands are visualized.

Statistics. Data are presented as the mean ±1 SD. Statistical significance of the differences between groups was determined by Student's *t* test.

RESULTS

Leukocyte counts. WBC and neutrophil counts for all patients studied are summarized in Table 1. The normal WBC count for normal adults in this laboratory is 4.8 to 10.8×10^6/mL, and the normal neutrophil count is 1.9 to 8.0×10^6/mL. The mean ± SD WBC count of all AIDS patients studied was $3.3 \pm 1.8 \times 10^6$/mL, for ARC patients $4.5 \pm 1.7 \times 10^6$/mL, and for PGL patients $5.0 \pm 0.6 \times 10^6$/mL. The mean ± SD absolute neutrophil counts were $2.1 \pm 0.9 \times 10^6$/mL, $2.5 \pm 1.2 \times 10^6$/mL, and $3.0 \pm 0.6 \times 10^6$/mL for the patient groups, respectively. The WBC and neutrophil counts were not significantly different between the three HIV-infected groups. There was no significant difference between the WBC or neutrophil counts of the homosexual and drug abuser groups studied or between homosexual patients with *Pneumocystis carinii* pneumonia (PCP), Kaposi's sarcoma (KS), or other opportunistic infections (OIs). The WBC and neutrophil counts of AIDS and

Table 1. Leukocyte and Neutrophil Counts of Patients

Patients* (n)	Leukocyte Count (Range)	Neutrophils (Range)
AIDS (53)	3.3 ± 1.8 (1.0-8.6)	2.1 ± 0.9 (0.1-7.5)
ARC (20)	4.5 ± 1.7 (2.8-7.0)	2.5 ± 1.2 (1.2-4.8)
PGL (5)	5.0 ± 0.6 (4.2-5.9)	3.0 ± 0.6 (2.4-3.8)
AIDS, by risk group†		
Homosexual (38)	3.3 ± 1.6 (1.0-7.7)	2.1 ± 0.98 (0.13-4.2)
IVDA (13)	3.6 ± 3.4 (1.6-8.6)	3.4 ± 3.1 (1.2-7.5)
Hemophiliac (1)	1.5	0.7
Wife of IVDA (1)	5.0	4.0
Homosexuals with AIDS, by infection/neoplasm‡		
PCP (16)	2.9 ± 1.4 (1.1-5.2)	2.1 ± 1.3 (0.13-4.2)
Other OI (14)	3.5 ± 2.2 (1.0-7.7)	1.9 ± 0.8 (0.67-3.3)
KS (8)	3.9 ± 0.6 (1.1-5.2)	2.3 ± 0.4 (1.8-2.6)

Neutrophil counts are mean count × 10^6 ± 1 SD/mL. Normal leukocyte count = 7.8 (4.8-10.8) × 10^6/mL; normal neutrophil count = 4.0 (1.9-8.0) × 10^6/mL.

*Differences between AIDS and ARC counts were not significant.

†Differences between leukocyte and neutrophil counts of homosexuals and IVDA were not significant.

‡Differences between leukocyte and neutrophil counts of homosexuals with PCP, and other OIs, and KS were not significant.

ARC groups were significantly reduced when compared with those of the normal population ($P < .01$).

CFU-GM proliferation. As shown in Fig 1, BM cells from 53 AIDS patients, 20 ARC patients, and 5 PGL patients each generated significantly fewer CFU-GM colonies than did controls ($P < .01$). No significant differences were noted among AIDS, ARC, and PGL patients, among the various risk groups with AIDS described above, or when the patients with AIDS who had PCP, other OIs, or KS without OI were compared ($P > .5$ for each comparison), although each group was significantly reduced when compared with normal subjects ($P < .01$).

Coculture and FLs. Control PB-MNCs were cultured for CFU-GM in the presence of 10% serum from AIDS

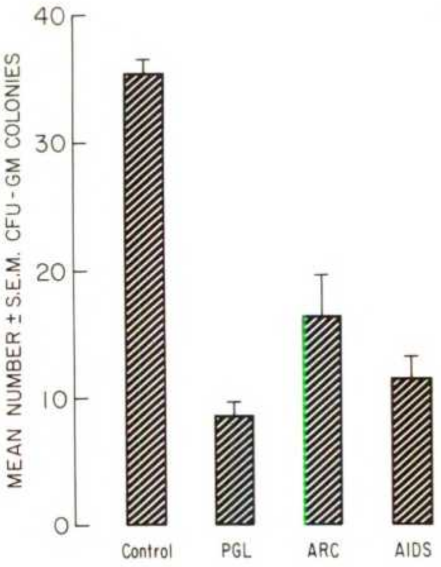

Fig 1. Comparison of growth of the granulocyte-macrophage progenitor cell colonies (CFU-GMs, mean ± SEM) from 9 healthy controls (35.7 ± 1.5), 5 patients with PGL (8.6 ± 1.1), 20 ARC (16.4 ± 3.2), and 53 AIDS (11.32 ± 1.7). There was a statistically significant difference ($P < .001$) in the number of CFU-GM colonies between the control group and each of the three groups of patients, but not between the patient groups. There was no significant difference between the patient groups. Within the AIDS group, there was no significant difference between the patients with an opportunistic infection (treated or untreated) and those with a neoplasm characteristic of AIDS (not shown). No patients had received antineoplastic chemotherapy prior to being studied.

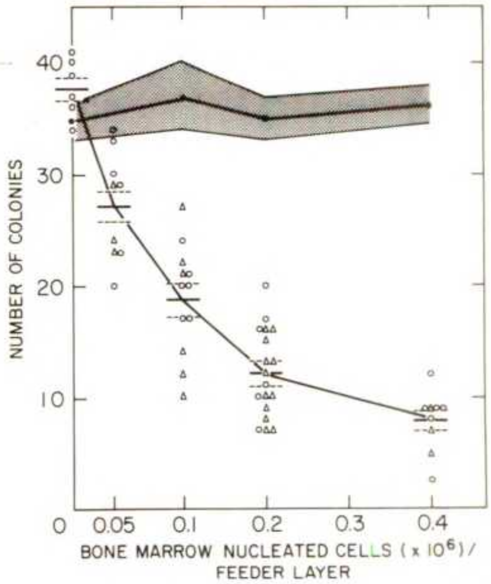

Fig 2. Dose-related inhibition of control CFU-GMs by BM-nucleated cells from AIDS patients. BM-nucleated cells from patients (n = 10) with AIDS were isolated in FLs at concentrations of 0.05, 0.1, 0.2, and 0.4 × 10^6 cells/mL and overlayered with 0.2 × 10^6 control BM-nucleated cells (○) or PB-MNCs (△). These control cells had progressive decreases in colony growth of 20.2%, 44.2%, 68.1%, and 80.1%, respectively, when compared with control cells grown over FLs devoid of cells (heavy lines are the mean number of colonies; broken lines are the SEM). Mean number of colonies grown over FLs containing normal control BM nucleated cells (●) (shaded area denotes SEM). The decrement seen for each group was significantly different ($P < .001$) from values for control cells grown over cell-free FLs or FLs containing 0.2 × 10^6 control BM cells.

patients. No difference was seen between these cultures and those cultured with or without heterologous control serum (data not shown). In contrast, coculture of AIDS BM-nucleated cells with control PB-MNCs in 0.3% agar revealed significant, sometimes total, colony growth inhibition ($P < .001$).

When FLs containing varying numbers of AIDS-BM nucleated cells were overlayered with 1×10^6 control PB-MNCs, CFU-GM growth at maximal inhibition was similar to that from the BM cells from the AIDS patients. Decreased colony formation by the control cells was seen in a dose–response fashion with increasing concentrations of patients' cells (Fig 2).

Conditioned media. Cell-free CM prepared from the BM-nucleated cells from eight patients with AIDS and two controls were added to the FLs at a final concentration of 10% in place of BM cells. The CM from all the AIDS patients significantly ($P < .001$) inhibited the CFU-GM growth of normal PB-MNCs in the same fashion as did AIDS BM-nucleated cells. Control CM had no effect on the cultures. After ammonium sulfate precipitation of the AIDS CM, the inhibitory activity was recovered from the precipitates (Fig 3) but not from the supernatants (not shown). Again, control CM showed no inhibitory activity in either fraction.

PAGE. The ammonium sulfate precipitates of the patients' and controls' CM were run in 7.5% polyacrylamide gels. A unique band was observed in the lanes containing the patients' CM but was absent in the control lanes (Fig 4). This protein, absent in the control lanes, had a relative molecular mass of 84 kd as determined by SDS-PAGE (Fig 4). PAS staining of these gels revealed a gp band in the same region as the unique band, but the 84-kd region was PAS negative in the control lanes.

The proteins were electrophoretically eluted from serial slices of 7.5% preparative PAGE. The proteins isolated in this manner had inhibitory activity in the CFU-GM assay in the same fashion as described for the CM. The inhibitory activity was recovered from proteins eluted from the region of the gel that contained the unique band (Fig 3). No other proteins with inhibitory activity were recovered from any other region of these lanes or from control lanes.

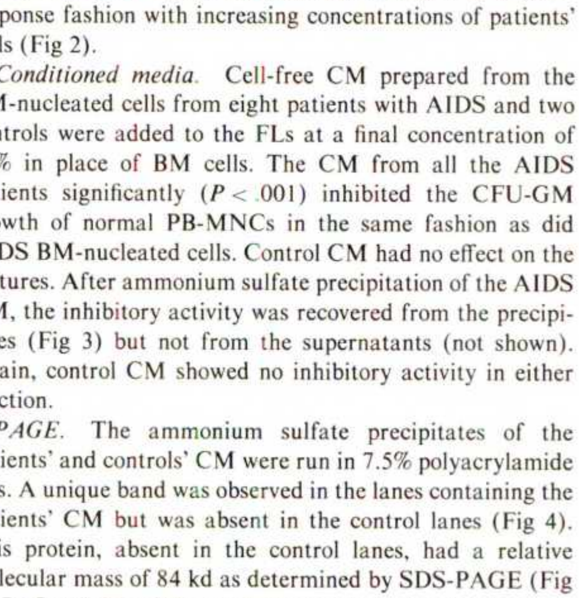

Fig 3. Control CFU-GM colony growth (mean ± SEM) over FLs that were without cells or CM (36.25 ± 1.1) or contained CM prepared from control BM cells (35.7 ± 1.5), 0.2×10^6 BM-nucleated cells from patients with AIDS (12.1 ± 2.0), CM prepared from AIDS BM cells (6.0 ± 0.6), resolubilized ammonium sulfate precipitate from AIDS BM CM (3.3 ± 0.7), and electrophoretic eluates of 84-kd bands from PAGE-separated CM (2.0 ± 1.2).

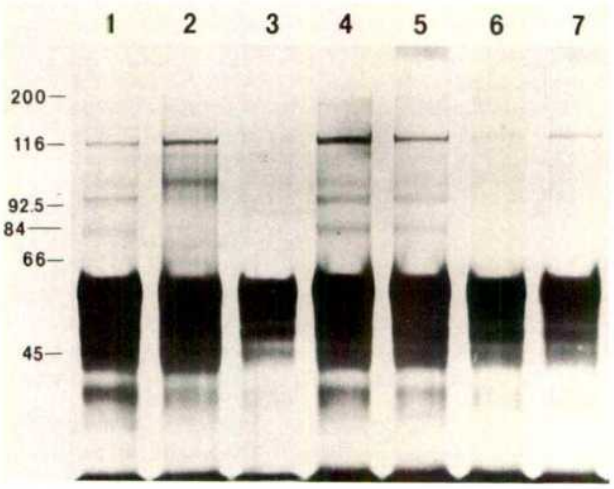

Fig 4. Resolubilized ammonium sulfate precipitates of CM were electrophoresed into a 7.5% SDS-polyacrylamide gel and silver stained to visualize the separated proteins. Lanes 1, 2, and 4 contained CM prepared from bone marrow (BM) cells of three different patients with AIDS. Lane 5 contained CM from a patient with ARC. Lane 7 contained CM from a healthy HIV-seronegative male homosexual. Lanes 3 and 6 contained CM from two different normal controls.

Western blotting. Resolubilized ammonium sulfate precipitates of CM were electrophoresed into 7.5% SDS-PAGE and were then blotted as described. The blotted proteins were then probed with polyclonal and monoclonal antibodies raised against HIV antigens (generously provided by Drs Robert Gallo and S. Zaki Salahuddin of the National Cancer Institute). The 84-kd band was not recognized by any of these antibodies.

DISCUSSION

Leukopenia and neutropenia are frequent findings in patients within the AIDS spectrum. To elucidate the mechanism of the neutropenia, we assessed the proliferation of CFU-GMs from the BM cells of 78 patients within the AIDS spectrum (AIDS, ARC, and PGL). BM cells from 70 of 78 patients made significantly fewer CFU-GM colonies than did controls ($P < .01$).

The number of CFU-GM colonies from groups of patients with AIDS, ARC, or PGL were not statistically significantly different from each other, indicating that this decrease was not related to the severity of clinical disease. Statistical comparison of the number of CFU-GMs among the various risk groups also showed no significant differences. Homosexual men, the largest group of AIDS patients we studied, were further divided into three subgroups: those with PCP, other OIs, or with KS with no OI. No significant differences were seen between these subgroups in the number of CFU-GM colonies, indicating that there was no relationship to any type of secondary infection or malignancy. Of particular interest, 60% of the patients with PCP but none of the others had been treated with trimethoprim-sulfamethoxazole. Although this drug combination has been well documented to cause neutropenia and AIDS patients have been reported to be especially sensitive,[6] these results from the various subgroups indicate that the neutropenia and reduced CFU-GMs in our patients were not consequent to such drug therapy. The apparent exquisite sensitivity to the drug may be the result of a background of preexisting defective granulopoiesis with little or no reserve capacity when even minor additional suppression is superimposed.

Coculture of control PB-MNCs with AIDS BM cells revealed a profound decrease in the number of colonies formed. To determine whether this decrease in CFU-GM colony growth was due to a cell–cell interaction or to a factor released by the cells into the culture milieu, patients' BM-nucleated cells were immobilized in a FL without CSF, over which the control cells were cultured with added CSF. Because the normal CFU-GMs can be progressively inhibited with increasing concentrations of physically separated patients' cells in the FL, we established the humoral nature of the suppression.

To identify further the factor(s) responsible, CM were obtained from liquid cultures of AIDS BM-nucleated cells. CM added to cell-free FLs inhibited growth to a degree comparable to coculture with BM cells (Fig 3). The inhibitory factor was precipitated by 50% ammonium sulfate. PAGE analysis of the CM precipitate and PAS staining revealed that the inhibitory factor is a gp with a relative mol wt of 84 kd. The 84-kd bands electrophoretically eluted from the gels had inhibitory activity identical to that of the CM.

We previously reported that excessive margination of neutrophils was not found in AIDS pateints and that five of six AIDS patients had a decreased mobilizable BM neutrophil storage pool in vivo.[23] Morphological observations of BM biopsies confirmed a decrease in the mature neutrophil pool.[24] Because the fraction of BM myeloid precursors in DNA synthesis was within the normal range, BM granulopoiesis may not respond appropriately to the neutropenia. Although our data from in vitro cultures cannot be directly compared with the above observations in vivo, the decrease in the BM storage pool of mature neutrophils could be explained at least in part by inhibition of stem cell activity. The inhibitory activity on BM neutrophil progenitors demonstrated in vitro might also affect more mature precursors. The decrease in the storage pool, in turn, would explain a profound decrease in CFU-GMs associated with a less profound decrease in blood neutrophils since one can maintain blood neutrophils at the expense of the storage pool.

Donahue et al[25] have reported that sera and immunoglobulins from HIV-infected individuals suppressed CFU-GMs and BFU-Es from AIDS and ARC patients but not from healthy controls. They observed that antibodies against the HIV envelop gp130, inhibit CFU-GM, thus suggesting that this antibody reacts with HIV infected progenitors and suppresses them. Similarly, we found that sera from patients with AIDS had no effect on CFU-GMs from healthy controls, but the novel gp that we report here differs from the findings of Donahue et al since it is not an immunoglobulin and is not cross-reactive with antibodies against HIV. In other unpublished studies, we found no evidence of inhibition of BM cells or PB BFU-Es or CFU-Es by control or patient CM. In addition, CM added to control PB-MNCs stimulated with varying concentrations of phytohemagglutin, pokeweed mitogen, and concanavalin-A did not decrease the blastogenic response to these mitogens. Thus, the specificity of gp84 is different from that reported by Donahue et al and from an inhibitor of lymphocyte proliferation in AIDS patients described by Laurence and Mayer.[26] Our Western blot data do not preclude the possibility that gp84 is an HIV product, although it is more likely a secondary product of HIV infection.

Inhibitors of CFU-GMs have been well described in numerous acute diseases and syndromes.[27-30] Many of these inhibitors are T lymphocyte-mediated,[31-34] whereas others are factors released by other specific cell populations.[35-41] The gp that we demonstrated has different physiochemical characteristics from these previously described factors.

FeLV, a retrovirus with similarities to HIV, induces an immune-deficient state in some infected cats, many of whom are neutropenic as well.[42,43] These infected, neutropenic animals have a decrease in the number of BM CFU-GMs, although no explanatory mechanism has been proposed.[44] Conceivably, the neutropenia secondary to FeLV infection is analogous to the neutropenia associated with AIDS.

Our demonstration of a gp that inhibits granulopoiesis in vitro possibly provides an explanatory mechanism for previous observations of neutropenia in patients within the AIDS spectrum.

Preliminary experiments suggesting the specificity of the inhibitor raise the possibility that a series of specific viral products or virally induced products may explain some of the many cellular defects observed in these patients. The lack of reactivity with known antibodies to HIV suggests that gp84 is not a viral constituent, although gp84 may be produced by a population of BM cells in response to HIV infection.

Molecular Genetic Survey of 16 Kindreds With Hereditary Antithrombin III Deficiency

By Susan Clark Bock and Edward V. Prochownik

Molecular genetic techniques were utilized to examine antithrombin III (ATIII) gene status in 16 independently ascertained kindreds with hereditary ATIII deficiency. In one of these families antithrombin III deficiency is caused by hemizygosity of the ATIII locus. In the remaining 15 kindreds, two copies of the ATIII gene are present and appear to be grossly normal at the level of whole genome Southern blotting, suggesting that small deletions, insertions or limited nucleotide substitution(s) in the antithrombin III gene, or "trans-acting" defects at other loci involved in the processing, modification, and secretion of biologically active ATIII are responsible for the observed anticoagulant disorders.

© 1987 by Grune & Stratton, Inc.

ANTITHROMBIN III (ATIII) is a plasma glycoprotein that is in large part responsible for maintaining the fluidity of blood. It inhibits thrombin and other activated proteinases of the coagulation cascade by forming stoichiometric 1:1 inhibitor–enzyme complexes with them.[1] The rate of antithrombin III-mediated thrombin inactivation is modulated by the acidic mucopolysaccharide heparin, increasing by over three orders of magnitude in the presence of this cofactor.[1]

Studies of families with inherited antithrombin III deficiency have provided evidence that ATIII is an important physiologic inhibitor of thrombin.[2] Affected individuals in such families have functional anticoagulant levels that are about 50% of normal and tend to suffer recurring episodes of pulmonary embolism and deep vein thrombosis during adult life. More than 50 families with ATIII deficiency have been reported in the literature (see Thaler and Lechner[3] for review). The human ATIII structural gene locus maps to chromosome 1, subregion 1q23-q25,[4] and the mode of inheritance in all cases of ATIII deficiency studied so far is autosomal dominant.

Two categories of ATIII deficiency have been defined on the basis of ATIII antigen levels in the plasma of affected individuals. The majority of ATIII deficiency kindreds belong in the type I ("classical") deficiency group[5] and have a quantitatively abnormal phenotype in which antigen and heparin cofactor levels are both reduced to about 50% of normal. Possible molecular genetic explanations for type I deficiencies include complete or partial deletion or rearrangement of one ATIII allele or mutations that interrupt anticoagulant biosynthesis at the RNA or protein level.

The second category of ATIII deficiency affects about 20% of families with hereditary thrombosis[6] and has been termed type II ("functional") deficiency.[5] Affected individuals from these kindreds produce dysfunctional ATIII molecules; they have reduced heparin cofactor activity levels (approximately 50% of normal) but levels of ATIII antigen are often normal or nearly normal.[7-9] In addition, variant ATIII molecules, but not thrombotic symptoms, are inherited in several other families.[20-23] Studies of dysfunctional and variant ATIIIs have shown that the abnormalities in ATIII molecules from different kindreds are heterogeneous, and the amino acid substitutions responsible for dysfunction have been identified in four cases.[16,24-26]

cDNA clones for human ATIII have been isolated,[27-29] and the structure of the gene has been determined.[30] In addition, two restriction fragment length polymorphisms in the ATIII locus have been identified.[31,32] The availability of probes, a map, and linkage markers for the ATIII gene have made it feasible to use a molecular genetic approach to study the origins of ATIII deficiency in affected families. This communication reports the initial results of a survey on 16 different kindreds that segregate hereditary ATIII deficiency.

METHODS

ATIII deficient families. Family histories, hematologic data, and blood samples were kindly supplied by Drs K. Bauer (Boston), J. Brandt (Columbus, OH), J. Chediak (Chicago), J. Lewis (Pittsburgh), J. Rand (New York), M. Skolnick (Salt Lake City), J. Weitz (New York), and G. White and J. Griffith (Chapel Hill, NC). Reports on kindreds RU54,[10] RU 90,[19,24,33] CH1 and CH2,[31] and CH6[34] have appeared previously in the literature.

Preparation of genomic DNA and Southern blots. High mol wt genomic DNA samples were prepared as previously described[19,30] from 30-cc blood samples anticoagulated with EDTA or acid-citrate-dextrose. Five-to 15-microgram DNA samples were digested with the indicated restriction enzymes and used to prepare Southern blots[35] on nitrocellulose or nylon filters following electrophoresis through 0.8% or 1.0% agarose gels. The Southern blots were hybridized to antithrombin III cDNA probes[27,28] that had been labeled to high specific activity by nick translation with ^{32}P.

Gene dosage studies. ATIII gene dosage was determined in several different ways. In some individuals the presence of two ATIII alleles could be visualized directly on Southern blots using alleles of the ATIII sequence[31] and length[32] DNA polymorphisms as linkage markers. Similarly, a family study of DNA polymorphism segregation was used to demonstrate the deletion of one ATIII allele in one kindred.[31] Finally, quantitative ATIII gene dosage studies were performed on those families in which all available affected individuals were not heterozygous for either of the restriction fragment length polymorphisms (ie, they were either homozygous or

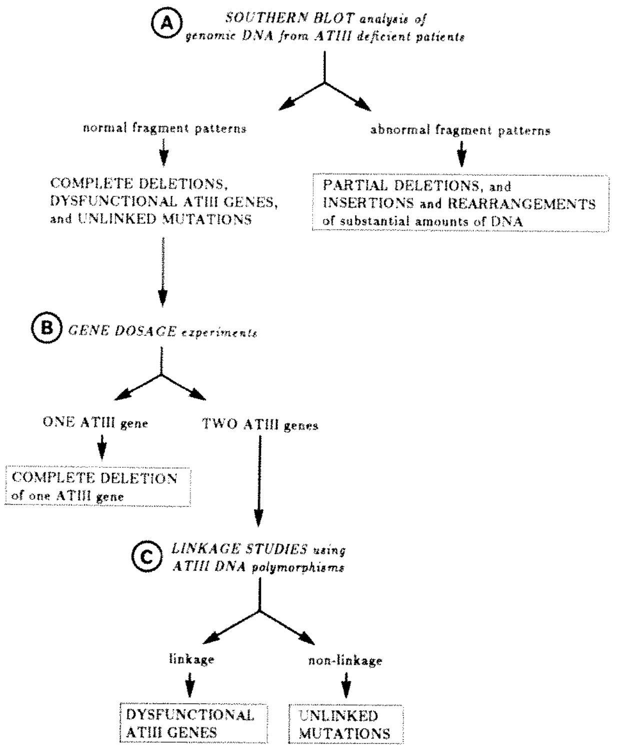
hemizygous at these markers). In these studies Southern blots were hybridized to a mixed probe containing human ATIII[27] and C$\bar{1}$ inhibitor[36] cDNA sequences. ATIII is located in subregion q23-q25 of chromosome 1,[4] while C$\bar{1}$ inhibitor maps to chromosome 11, q12-q13.1.[45] C$\bar{1}$ inhibitor thus serves as an internal gene dosage and blotting control in this protocol. Control DNA for the quantitative gene dosage experiment was extracted from cultured fibroblasts of the GM2025 cell line (del 1q21-1q25; Human Genetic Mutant Repository, Camden, NJ). Following autoradiography films were scanned on a densitometer.

RESULTS

The flow chart shown in Fig 1 depicts the experimental scheme used to study ATIII gene status in families with hereditary ATIII deficiency. Table 1 summarizes the results of our work on 16 such families.



A
SOUTHERN BLOT analysis of genomic DNA from ATIII deficient patients
normal fragment patterns
abnormal fragment patterns
COMPLETE DELETIONS, DYSFUNCTIONAL ATIII GENES, and UNLINKED MUTATIONS
PARTIAL DELETIONS, and INSERTIONS and REARRANGEMENTS of substantial amounts of DNA
B
GENE DOSAGE experiments
ONE ATIII gene
TWO ATIII genes
COMPLETE DELETION of one ATIII gene
C
LINKAGE STUDIES using ATIII DNA polymorphisms
linkage
non-linkage
DYSFUNCTIONAL ATIII GENES
UNLINKED MUTATIONS

*Method of gene dosage determination: Quantitative dosage blot.

†Method of gene dosage determination: DNA polymorphism heterozygosity in affected individual.

‡Method of gene dosage determination: Family study using DNA polymorphism.

Absence of gross abnormalities in the ATIII gene. Southern blot analysis (experiment A on flowchart, Fig 1) can resolve gross alterations in a locus of interest, since the deletion, insertion, or rearrangement of a substantial amount of DNA ($>\sim$100 bp) will alter the distance between adjacent restriction sites and generate new hybridizing fragments with unusual mobilities. A battery of restriction enzymes (BamHI, EcoRI, HindIII and PstI) known to cleave collectively at fairly regular intervals throughout the ATIII locus[30] was used to digest normal and patient DNAs. Southern blots were prepared and hybridized to an ATIII cDNA probe. In the blot shown in Fig 2 and others, the patterns of hybridizing fragments obtained from DNAs of affected individuals in all 16 deficiency kindreds were qualitatively identical to those produced by DNAs from normal relatives and controls after variations caused by commonly occurring DNA polymorphisms had been accounted for. These data indicate that ATIII deficiency in these families is not caused by insertion or rearrangement of a substantial amount of DNA in the ATIII locus or partial deletion of the gene but suggest (1) complete deletions, (2) point mutations, or (3) *trans*-acting, unlinked mutations as possible causes of hereditary thrombosis.

Antithrombin II gene dosage in ATIII deficient families. The next stage in our analysis of ATIII deficiency was to determine ATIII gene dosage in the 16 families with hereditary thrombosis (experiment B on flowchart, Fig 1). The issue of whether hemizygosity of the ATIII locus was responsible for reduced antithrombin levels was assessed (1) by using ATIII DNA polymorphisms as linkage markers for specific antithrombin III alleles and (2) through quantitative Southern blot experiments.

Two two-allele DNA polymorphisms[31,32] have been identified with ATIII cDNA hybridization probes. The "+" and "−" alleles of the PstI sequence polymorphism generate a hybridizing 5-kb doublet and a 10-kb band, respectively (Fig 3 A), while the "F" and "S" alleles of the length polymorphism produce 1450 and 1550 nucleotide BamHI fragments, respectively (Fig 3 B). Figure 3 C shows blots prepared with PstI- (top) and BamHI-cleaved DNA (bottom) from two affected members of the RU52/56 kindred. The DNA sample from patient 1 produced a 10-kb PstI band and a 1450 nucleotide BamHI fragment. This pattern is consistent with the presence of one or two −,F haplotype alleles. However, polymorphism analysis of DNA from another

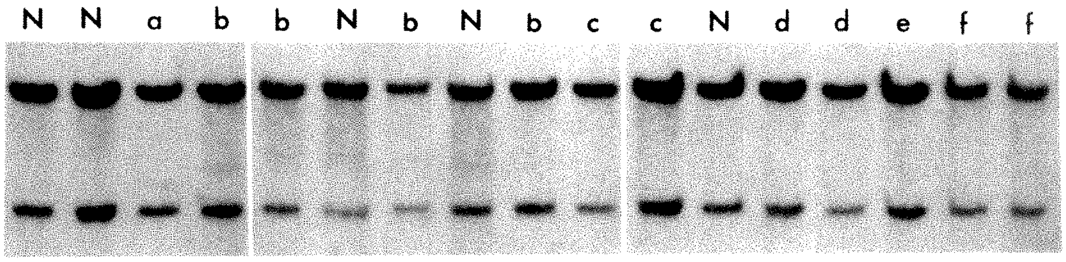

Fig 2. Southern blot of DNAs from normals and ATIII-deficient patients. The blot was prepared with EcoRI-digested genomic DNAs and hybridized to ^{32}P-labeled ATIII cDNA insert sequences. Each lane shown contains DNA from a different individual. N, normals; *a*, affected patient from RU51; b, four affected patients from RU52/56; c, two affected patients from RU53; d, two affected patients from RU54; e, affected patient from RU55; f, two affected patients from RU90.

affected member of the family, patient 2, showed that deletion of one ATIII gene has not occurred in this kindred. The presence of two ATIII genes can be directly visualized in individual 2 as heterozygosity at both the sequence and length polymorphisms. Identification of affected individuals who are heterozygous at one or both ATIII DNA polymorphisms was also used to exclude hemizygosity as the cause of antithrombin III deficiency in CH2,[31] CH4, CH5, CH6, and RU90.[19] Similarly, inheritance of DNA polymorphisms was used to demonstrate hemizygosity of the ATIII locus in another family. The presence of a null allele was deduced by monitoring the segregation of the PstI sequence polymorphism in CH1 and established that the hereditary tendency to thrombosis in this kindred is due to complete deletion of one ATIII allele.[31]

Quantitative blotting experiments were used to determine ATIII gene dosage in the families in which analysis of ATIII DNA polymorphisms was not productive due to the lack of marker heterozygosity in available affected patients. Southern blots prepared from HindIII-digested DNAs were hybridized to a mixed probe containing ATIII cDNA and C$\bar{1}$ inhibitor cDNA sequences. The latter probe, which maps to chromosome 11,[36] is unlinked to ATIII (which maps to chromosome 1[4]) and served as a DNA dosage and transfer control in this experiment. Autoradiograms of the blots were scanned on a densitometer and normalized so that the intensities of the 4-kb bands resulting from control probe hybridization equaled 100%. Some traces are shown in Fig 4. When samples from affected individuals in the RU51, RU53, RU54, RU55, RU57, RU58, RU59, RU60, and CH3 pedigrees were analyzed, intensities of the 2.2-kb and 2.5-kb ATIII fragments were equal to those of the corresponding bands in samples from unaffected, normal controls and double those observed in a sample from the ATIII deletion control GM2025 (del 1q21-1q25). Therefore, two ATIII genes are present in patients from these nine families, and hemizygosity of the antithrombin III locus is not the cause of anticoagulant deficiency. Analysis of a sample from CH1, however, reconfirmed that affected patients in this family have only one ATIII gene.[31]

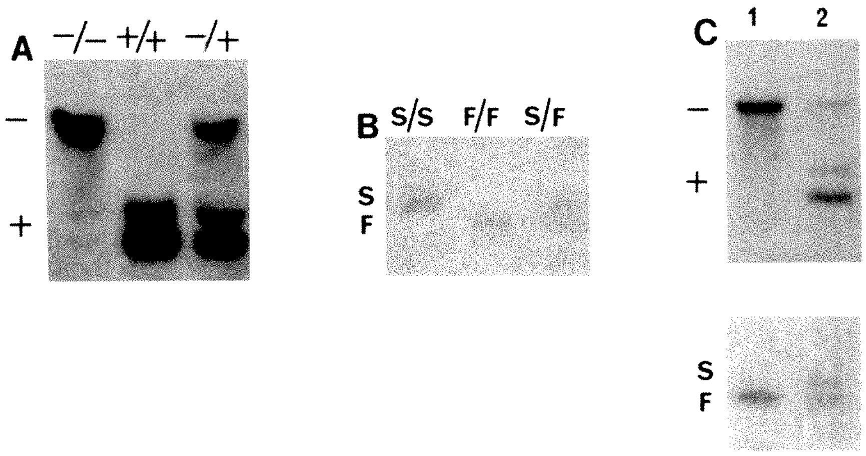

Fig 3. Use of ATIII DNA polymorphisms to determine antithrombin III gene dosage. Southern blots were prepared from PstI- (a and c, top panel) and BamHI- (b and c, bottom panel) digested DNAs and hydridized to ^{32}P-labeled ATIII cDNA sequences. (a) Sequence polymorphism. "−/−" homozygotes produce a 10-kb band (left), while "+/+" homozygotes generate a 5-kb doublet (center), and "−/+" heterozygotes produce a composite pattern (right) in which bands are approximately one half as intense as in homozygotes. (b) Length polymorphism. "S/S" homozygotes produce a 1550-bp band (left), "F/F" homozygotes a 1450-bp band (center), and "S/F" heterozygotes show both fragments at reduced intensity (right). (c) Affected individuals in kindred RU52/56 have two copies of the ATIII gene. Sequence polymorphism data are shown in the top panel and length polymorphism data in the bottom panel. The haplotype of patient 1 could be "−,F/−,F" or "−,F/null". However, the haplotype of patient 2 is "−,F/+,S", indicating that deletion of one ATIII allele has not occurred.

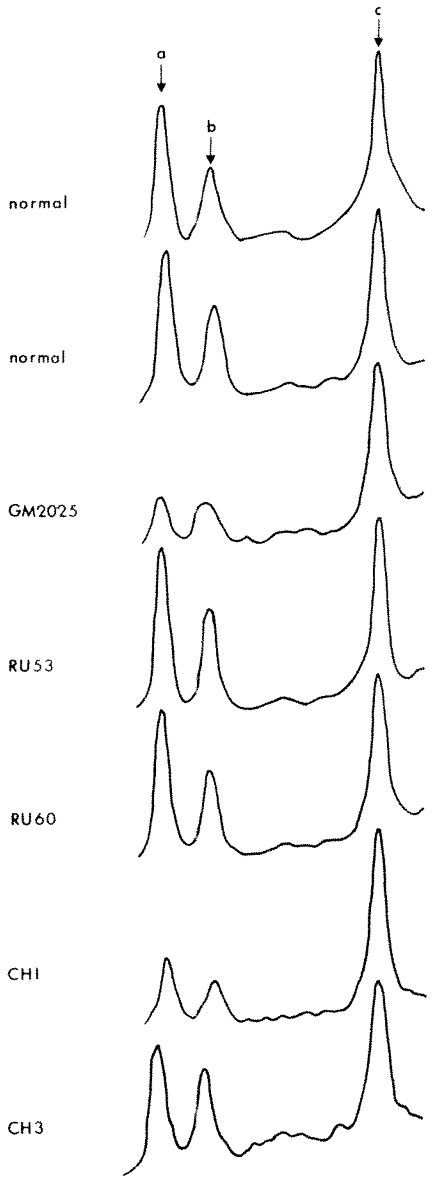

Fig 4. Quantitative ATIII gene dosage experiment. Southern blots were prepared from the indicated HindIII-digested genomic DNAs and hybridized to a mixed probe containing ATIII and C$\overline{1}$ inhibitor cDNA sequences. Following autoradiography the film was scanned on a densitometer. Peaks a and b are 2.2- and 2.5-kb bands resulting from hybridization to the ATIII cDNA probe. Peak c is a 4-kb band resulting from hybridization to the C$\overline{1}$ inhibitor control probe, and its height has been normalized to 100% in the tracings shown. Intensities of peaks a and b from patient samples of RU53, RU60, and CH3 correspond to those observed in normals and indicate that two copies of the antithrombin III gene are present. Complete deletion of one ATIII allele in the deletion control sample (GM2025, del 1q21-q25) and in ATIII deficiency kindred CH1 is indicated by reduced intensity of peaks a and b in these scans.

DISCUSSION

Table 1 summarizes the results of our series of 16 ATIII deficiency families. Complete deletion of the ATIII locus has occurred in one case (CH1). Affected members of this family have reduced functional activity and immunologic levels of ATIII, and one individual has experienced deep vein thrombosis. Half normal levels of antithrombin III have also been observed in patients with large, cytologically visible deletions of 1q (del 1q22-q25 and del 1q21-q25).[37]

Major structural gene alterations (partial deletions, rearrangements, and duplications) have been established as the molecular causes of genetic disease in certain patients with thalassemia,[38] Lesch-Nyhan syndrome,[39] apolipoprotein AI deficiency,[40] and hemophilia.[41] However, among the families we studied there were no examples of large gene alterations in the ATIII locus causing anticoagulant deficiency. The hybridization patterns of normal and patient DNAs were determined using four different restriction enzymes that are known to cleave collectively at fairly regular intervals throughout the ATIII gene, and we believe that changes affecting ≥100 bp of DNA would have been detected.

Affected individuals in 15 of the 16 families surveyed here had two ATIII genes. In these cases ATIII deficiency may be caused by a small mutation in the ATIII gene itself or by a defect in a transacting factor involved in the synthesis, maturation, or secretion of the functional anticoagulant molecule. These two alternatives can be distinguished by linkage tests (experiment C on flowchart in Fig 1). In the case of dysfunctional ATIII genes, ATIII deficiency will cosegregate with a given ATIII allele (which can be recognized by its DNA polymorphism haplotype). The disorder and specific ATIII alleles will show unlinked inheritance in the cases in which anticoagulant deficiency is caused by the dysfunction of a transacting factor or the gene encoding it. Since only two two-allele DNA polymorphisms have been identified in the ATIII locus (combined polymorphism information content = 0.45[19]), extensive family studies are required to confidently distinguish the dysfunctional gene and unlinked mutation alternatives and have been completed in only one case so far (RU 90).

RU 90 is a large Utah kindred in which 13 members in 3 generations have had ATIII deficiency. This family was originally described as a type I deficiency, since ATIII antigen and activity levels are both reduced to approximately 50% of normal.[33] However, subsequent immunoblotting experiments revealed the presence of very small amounts of a variant ATIII molecule in the plasma of Utah patients, and a maximum likelihood linkage study established that a dysfunctional gene residing on a chromosome of the +,S ATIII DNA polymorphism haplotype encodes this electrophoretically abnormal inhibitor.[19] The ATIII-Utah allele has been isolated by molecular cloning, and a C to T mutation has been identified in the second position of the codon for proline-407,[24,42] a highly conserved residue in the serine protease inhibitor gene family.[43] The resultant leucine for proline substitution may cause rapid turnover of the mutant gene product (due to incorrect folding) and/or loss of the ability to form functional inhibitor-protease complexes with thrombin (since proline-407 is located only 14 residues away from the reactive site arginine[44]).

Molecular genetic techniques have been used to survey ATIII gene status in a series of 16 kindreds with ATIII deficiency. Knowledge of the genetic heterogeneity and mutations underlying ATIII deficiencies will allow improvements in the diagnosis and treatment of affected individuals. Additionally, characterization of functionally abnormal ATIII molecules and the genes encoding them will contribute to our understanding of how this anticoagulant molecule works and how it is activated by heparin.

ACKNOWLEDGMENT

We thank members of the ATIII-deficient families and their physicians for participating in this study and Dr Stuart Orkin for support and helpful advice. The expert technical assistance of J.F.Harris, D.J. Levitan, J.A. Marrinan, and E. Radziejewska is gratefully acknowledged.

Oncoplacental Protein SP$_1$—A Constitutive and Inducible Late Differentiation Marker of the Human Myelomonocytic Lineage

By Markku Heikinheimo, Carl G. Gahmberg, Hans Bohn, and Leif C. Andersson

The oncoplacental protein SP$_1$ is found in large quantities in human placenta, amniotic fluid, and pregnancy serum. Low levels have been reported in association with malignancy but also in healthy nonpregnant individuals. By indirect immunofluorescence, fluorescence-activated cell sorting, and immunoprecipitation we here demonstrate the presence of SP$_1$ both on the surface and in the cytoplasm of human granulocytes but not in earlier myeloid progenitor cells in bone marrow. Lymphocytes did not contain the protein, and only trace amounts could be found in the cytoplasm of blood monocytes. A major glycoprotein with an apparent mol wt of 90,000 was obtained by immunoprecipitation of surface-labeled granulocytes. Cultivated blood monocytes, while adhering to surfaces or forming multinuclear giant cells, displayed a strong membrane and cytoplasmic expression of SP$_1$. Treatment of the myeloid leukemia cell line ML-2 with tetraphorbol acetate (TPA) strongly induced SP$_1$ in the membrane and cytoplasm as revealed by immunofluorescence and polyacrylamide gel electrophoresis (PAGE) of immunoprecipitates from lysates of surface radiolabeled cells. The induction of synthesis of SP$_1$ in TPA-treated cells was confirmed by immunoprecipitation from lysates of cells metabolically labeled with ^{35}S-methionine. Human lymphoblastoid and erythroleukemic cell lines did not express SP$_1$ either before or after induced differentiation. Thus SP$_1$ provides a late differentiation marker for the myelomonocytic lineage and is strongly induced during macrophage differentiation or by TPA treatment of ML-2 cells.

© 1987 by Grune & Stratton, Inc.

THE PREGNANCY-SPECIFIC β-$_1$-glycoprotein SP$_1$ is a glycoprotein with an apparent mol wt of 90,000, and it was originally isolated from human placenta.[1] While human serum normally contains very low amounts of the protein,[2] serum from women in the last trimester of pregnancy contains up to 300 mg/L.

Immunohistochemical investigations have revealed the presence of SP$_1$ in normal and malignant trophoblasts. SP$_1$ has also been detected immunohistochemically in tumor tissue of nontrophoblastic origin, such as in neoplasms of the breast and gastro-intestinal (GI) tract.[3] Syncytiotrophoblasts have been shown to synthesize SP$_1$ in organ and cell cultures.[4,5] SP$_1$ has also been reported to occur in cultured fibroblasts and amniotic epithelial cells.[6,7]

Inaba et al[8] used histocytochemical techniques and found that an antiserum against SP$_1$ reacted with human and monkey blood neutrophils. The antigen(s) responsible for this immunoreactivity was not further characterized.

We have now investigated the occurrence and the regulation of expression of SP$_1$ in human hematopoietic cells and in leukemia cell lines before and after induction of differentiation.

MATERIALS AND METHODS

Hematopoietic cells. Normal blood leukocytes were isolated from buffy coats of blood units kindly donated by the Finnish Red Cross Blood Transfusion Service. Normal bone marrow was recovered from pieces of ribs that had to be resected during open thorax surgery.

Fractionation of cells. Blood granulocytes were isolated by dextran sedimentation of buffy coats. The leukocyte-rich suspension was subjected to Ficoll-Isopaque density gradient centrifugation at 400 g for 30 minutes. The lymphocytes and monocytes were recovered from the interphase, while the granulocytes were recovered from the pellet as described.[9] Monocytes were purified by Percoll density gradient centrifugation[10] of blood mononuclear cells recovered by Ficoll-Isopaque gradient centrifugation.

Cell lines. The following human hematopoetic cell lines were studied: the erythroleukemic lines K562[11,12] and HEL[13], the myeloid cell lines ML-2[14] and HL-60[15], and lymphoblastoid cell lines established locally by Epstein-Barr virus (EBV) infection of normal blood B cells.

Cell culture and induction of cell differentiation. Monocytes were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum (FBS) and allowed to attach on glass coverslips that were used for immunofluorescent staining. Primary monolayer cultures of monocytes were detached with a rubber policeman and subcultured at high density for five days to form multinuclear giant cells on coverslips. HL-60 and ML-2 cells were cultivated at optimal densities for three to five days in the presence of 10^{-8} mol/L tetraphorbol acetate (TPA) or 10^{-7} mmol retinoic acid as described.[16] K562 and HEL cells were treated with 1.2 µg/mL sodium butyrate or hemin at 50 µg/mL as described.[17,18]

Immunofluorescence. Cytocentrifuged smears were fixed for five minutes in cold methanol (−20°C) to permeabilize the plasma membrane. The indirect immunofluorescence staining was done with 1 : 30 diluted rabbit anti-SP$_1$ (Dakopatts, Copenhagen, Denmark) followed by 1 : 20 diluted fluorescein isothiocyanate (FITC)-conjugated goat antirabbit antiserum. Double immunofluorescence staining was performed with the monoclonal antibody (MoAb) OKM-1[19] (Ortho, Raritan, NJ) and rabbit anti-SP$_1$ antiserum by using FITC-conjugated goat antimouse and rhodamine-conjugated goat antirabbit antisera, respectively.

Fluorescence-activated cell sorting. Normal bone marrow cells in suspension were stained in indirect immunofluorescence by rabbit anti-SP$_1$ antiserum. The cell suspension was fractionated on a FACS IV (Becton-Dickinson) cell sorter, and the positively stained and

unstained populations were identified from May-Grünwald–Giemsa-stained cytocentrifuged smears.

Cell surface labeling, metabolic labeling, and immunoprecipitation. Purified granulocytes and uninduced and induced ML-2 cells (50×10^6 cells) were radioactively surface-labeled by the periodate/NaB^3H_4 technique, as described previously.[20] After labeling, the cells were solubilized at 0°C in 1 mL of 0.15 mol/L NaCl-0.01 mol/L sodium phosphate, pH 7.4, containing 1 % Triton X-100. The samples were centrifuged at 10,000 g for 15 minutes and the supernatants recovered. Twenty-five microliters were used for slab gel electrophoresis and 100-μL aliquots for immunoprecipitation. For metabolic labeling of ML-2 cells the cultured cells were incubated in 5 ml methionine-free Eagle's minimum essential medium (MEM) containing 1 mCi ^{35}S-methionine for one hour. After a two-hour chase in normal medium the cells were collected, washed twice, and lysates prepared for immunoprecipitation. Part of the ^{35}S-methionine-labeled samples were subjected to lentil lectin-Sepharose chromatography and the α-methylmannoside-eluted fractions used for immunoprecipitation.

Immunoprecipitations with protein A-containing staphylococci were performed using 10 μL rabbit anti-SP_1 antiserum in the absence or presence of 10 μg SP_1 protein. The procedure has been described in detail previously.[21]

Polyacrylamide gel electrophoresis ^{3}H-labeled cells and the immunoprecipitates were electrophoresed on 8% polyacrylamide slab gels,[22] and the radioactive proteins were visualized by fluorography as described.[23]

RESULTS

When cytocentrifuge smears from normal blood leukocytes were stained by immunofluorescence with rabbit anti-SP_1 antiserum, a strong intracytoplasmic staining was seen in granulocytes. No staining was obtained with lymphocytes. The eosinophilic granulocytes also remained unstained. In bone marrow a strong positive reactivity was obtained only with cells of the granulocytic lineage. The earliest myeloid cells staining with anti-SP_1 antiserum were found to be promyelocytes. Metamyelocytes and mature neutrophils showed a strong reactivity. No staining was seen in the erythroid or megakaryocytic lineages (Fig 1 A).

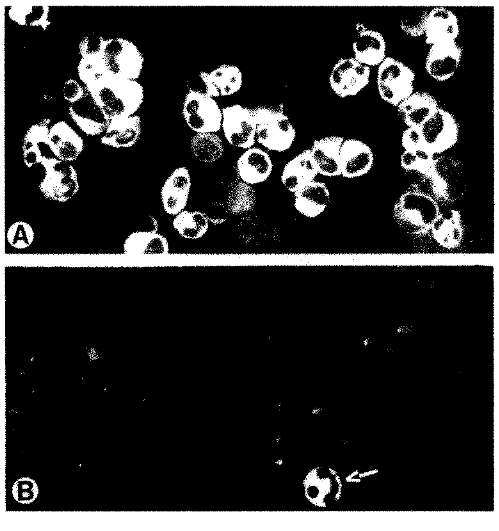

Fig 1. Immunofluorescence staining for SP_1 (rabbit anti-SP_1 antiserum) in normal bone marrow cells (A) and purified blood monocytes with one contaminating neutrophilic granulocyte (arrow, B).

Purified blood monocytes were negative in immunofluorescent surface staining, while a very faint, cytoplasmic reactivity, probably mainly in the Golgi area, could be seen in smears of monocytes (Fig 1 B).

Double-immunofluorescence surface staining with OKM-1 antibody and rabbit anti-SP_1 antiserum revealed a codistribution of these antigens as regards the granulocytic lineage, except that eosinophilic granulocytes were OKM-1 positive but SP_1 negative (figure not shown). Neither reagent detected early myeloblasts or cells of the erythroid lineage. Lymphoid cells were negative.

Sorting of anti-SP_1-stained bone marrow cells by a FACS IV revealed two populations (Fig 2 A). The positively staining cells consisted of mature granulocytes concentrating in the right shoulder of the histogram and their late precursors (Fig 2 C), while other bone marrow cells sorted in the unstained population (Fig 2 B).

When monocytes were allowed to adhere to a glass surface and were stained with anti-SP_1 antiserum, a strong intracytoplasmic reactivity was seen after only one day in culture (Fig 3 A). The staining intensity increased during the subsequent days of culture. Adherent monocytes forming multinuclear giant cells also displayed an intense and often asymmetrically distributed cytoplasmic and surface reactivity with the anti-SP_1 antiserum (Fig 3 C).

In the hematopoietic cell lines studied, SP_1 positivity was confined to the myeloid cell lines (ML-2 and HL-60). A very faint, hardly detectable, intracytoplasmic fluorescence like that in monocytes was seen in uninduced ML-2 (Fig 3 E) and HL-60 (not shown) cells. After treatment with TPA a very

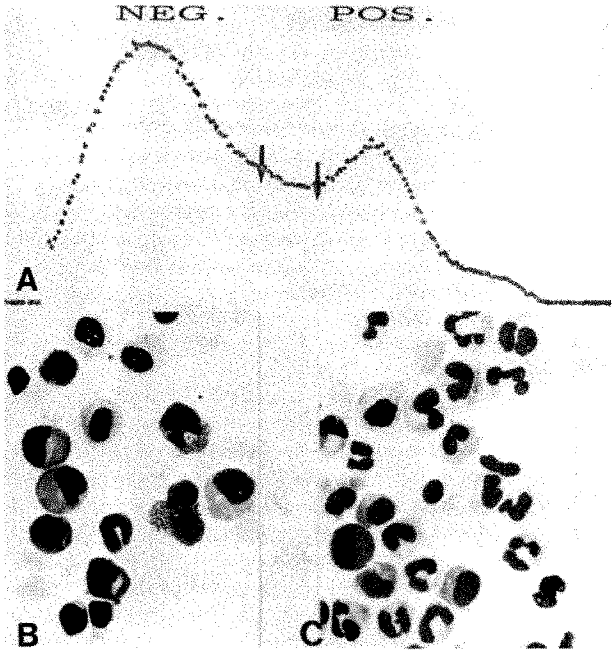

Fig 2. Fluorescence-activated cell sorting profile of normal human bone marrow utilizing rabbit anti-SP_1 antiserum (A). The SP_1 negative and positive cell populations are shown in B and C, respectively.

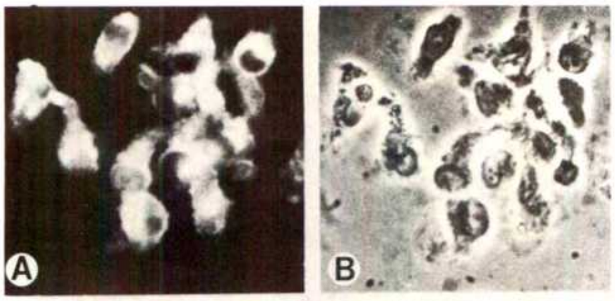

Fig 3. Immunofluorescence staining for SP$_1$ in adherent human monocytes (A), giant cells formed by monocytes (C), and the corresponding phase contrast microscopic presentations (B,D). The bottom figures show immunofluorescence staining for SP$_1$ in the myeloid cell line ML-2 before (E) and after (F) induction of cell differentiation by means of TPA.

strong membrane and cytoplasmic reactivity with anti-SP$_1$ was seen in ML-2 cells (Fig 3 F). TPA-treated HL-60 cells also showed an increased reactivity, while the lymphoblastoid and erythroleukemic cell lines did not stain with anti-SP$_1$ antiserum either before or after induced differentiation (not shown).

When immunoprecipitation was performed with anti-SP$_1$ antiserum from ^{3}H surface-labeled granulocytes and the precipitate electrophorized on polyacrylamide slab gels, two bands were seen. Most of the precipitated material displayed an electrophoretic mobility corresponding to an apparent mol wt of 90,000. In addition, a weaker band with an apparent mol wt of 54,000 was visualized (Fig 4 C). This might represent a proteolytic fragment. The addition of competing purified placental SP$_1$ protein to the lysate before the immunoprecipitation completely inhibited the specific reaction (Fig 4 D). Immunoprecipitation with anti-SP$_1$ antiserum from lysates of surface labeled, TPA-treated ML-2 cells gave a single band on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) of 90,000 mW (Fig 5 G). No band was visualized from untreated or retinoic acid-treated ML-2 cells (Fig 5 E,F).

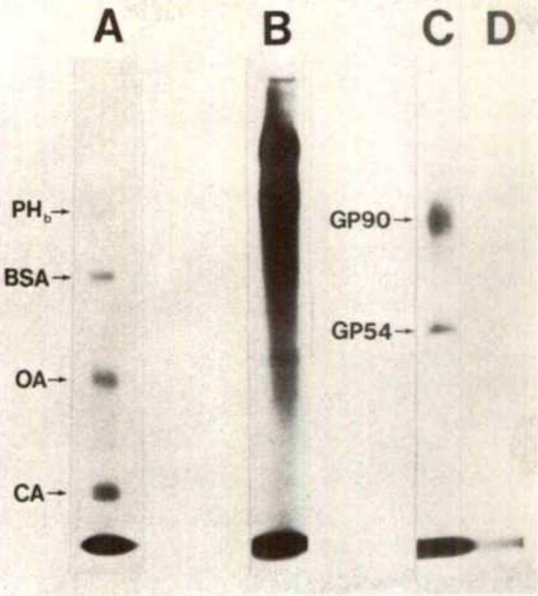

Fig 4. Polyacrylamide slab gel electrophoretic patterns of granulocyte surface glycoproteins reacting with anti-SP$_1$ antiserum. (A) Pattern of ^{14}C-labeled standard proteins: PH$_b$, phosphorylase b; BSA, bovine serum albumin; OA, ovalbumin; CA, carbonic anhydrase (B) Triton X-100 lysate is presenting the total surface-labeled glycoproteins of granulocytes. (C) Pattern of immunoprecipitate obtained with anti-SP$_1$ antiserum from surface-labeled granulocytes. (D) Pattern of immunoprecipitate obtained with anti-SP$_1$ antiserum from surface-labeled granulocytes in the presence of 10 μg unlabeled SP$_1$. GP90, surface glycoprotein with an apparent mol wt of 90,000; GP54, surface glycoprotein with an apparent mol wt of 54,000.

When lysates from TPA-treated ML-2 cells, metabolically labeled with ^{35}S-methionine, were immunoprecipitated with anti-SP$_1$, two bands of 80,000 and 90,000 apparent mol wt were seen (Fig 6 F). The lower band was enriched on lentil lectin-Sepharose columns (Fig 6 L), which shows its glycoprotein nature. The two bands are apparently not components of a heterodimeric molecule linked by disulfide bridges, since a similar polyacrylamide gel pattern was obtained under nonreducing conditions (not shown).

DISCUSSION

The SP$_1$ glycoprotein belongs to the family of glycoproteins that show elevated serum levels during pregnancy. Placental tissue has been shown to synthesize this protein in vitro and is therefore considered as the main source of the SP$_1$ during pregnancy. In this study we have shown that the SP$_1$ glycoprotein is present in blood leukocytes and constitutes a late differentiation marker for the myelomonocytic lineage. Although most of the antigen, as judged by immunoreactivity, is located intracytoplasmically, a surface expression can also be observed that allows positive selection of the later stages of the granulocyte lineage by fluorescent-activated cell sorting.

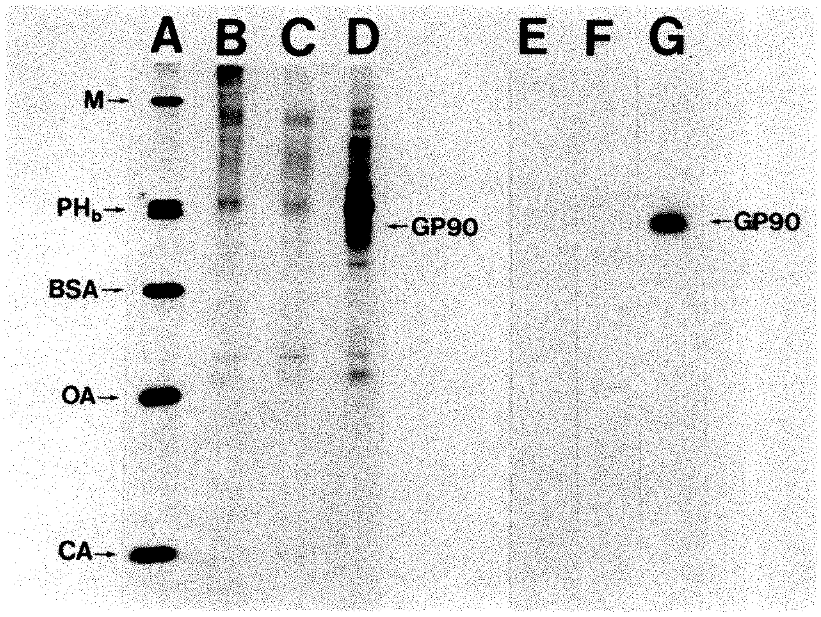

Fig 5. PAGE patterns of ML-2 cell surface glycoproteins reacting with anti-SP$_1$ antiserum. (A) Pattern of ^{14}C-labeled standard proteins, see legend to Fig 4; M, myosin. (B) Surface-labeled glycoproteins of untreated cells. (C) Surface-labeled glycoproteins of cells treated with retinoic acid. (D) Surface-labeled glycoproteins of cells treated with TPA. Twenty-five microliters of 1-mL lysates from 50 × 10^6 cells were loaded on B, C and D. (E) Immunoprecipitate obtained with anti-SP$_1$ antiserum from untreated cells. (F) Immunoprecipitate obtained with anti-SP$_1$ antiserum from cells treated with retinoic acid. (G) Pattern of immunoprecipitate obtained from cells treated with TPA.

The surface expression of SP$_1$ on granulocytes could further be substantiated by immunoprecipitation from lysates of surface-labeled, purified granulocytes. Analysis of the antigen precipitated by the anti-SP$_1$ antiserum on PAGE revealed a single major band of 90,000 apparent mol w. This corresponds to the mol wt reported for SP$_1$ of placental origin. Antigenic identity of the membrane protein in granulocytes and the SP$_1$ occurring in serum during pregnancy could be confirmed, since the addition of highly purified placental SP$_1$ could completely inhibit the immunoprecipitation with anti-SP$_1$ antiserum from surface-labeled granulocytes.

The availability of hematopoietic cell lines that phenotypically represent clonal expansions of certain lineages arrested at different stages of differentiation offers a useful tool for studies on biosynthetic events that are difficult to perform on limited amounts of available bone marrow cells. In this study we used a panel of hematopoietic cell lines that can be induced to further differentiation in vitro. Of these the promyelocytic cell line HL-60 and the myeloleukemia cell

line ML-2 expressed appreciable amounts of SP$_1$ after induced differentiation. The pluripotent leukemia cell line K-562 which, like the HEL line, has capacity of erythroid differentiation, and the lymphoid lines remained negative before and after induced differentiation.

As TPA treatment in vitro of ML-2 induced the most dramatic increase in the expression of SP$_1$, this model was selected for further investigations. As seen for differentiating granulocytes in normal bone marrow and for monocytes in culture, induction of ML-2 cell differentiation led to a strongly increased expression of SP$_1$ intracytoplasmically, but reactivity was also found with the cell surface. Metabolic labeling of the TPA-induced ML-2 cells by ^{35}S-methionine followed by immunoprecipitation and PAGE revealed two closely spaced bands of 90,000 and 80,000 apparent mol wt, respectively. The two bands did not represent components of a heterodimeric molecule linked by disulfide bridges, since two distinct similar bands were obtained by gel electrophoresis under nonreducing conditions. Immunoprecipitation from surface labeled ML-2 cells, on the other hand, revealed only a single band of 90,000 mol wt corresponding to that of higher mol wt obtained from metabolically labeled cells. It is possible that SP$_1$ occurs in two forms in hematopoietic cells where the intracytoplasmic protein has a slightly lower apparent mol wt. Alternatively, the 80,000-mol wt band observed after metabolic labeling might represent an incompletely glycosylated precursor of the membrane-expressed 90,000-mol wt antigen. Pulse-chase experiments with TPA-induced ML-2 cells are now in progress to distinguish between these two possibilities.

TPA is commonly used in induction of differentiation both of hematopoietic and nonhematopoietic cells. The mechanism of action of this compound is still incompletely understood. The ability of TPA to activate protein kinase C might be involved in the transduction of the differentiation signals. We have earlier shown that treatment of ML-2 cells with TPA induces distinct alterations in the surface glycoprotein pattern.[16] While untreated ML-2 cells contain hardly detectable amounts of SP$_1$, treatment with TPA led to a strong increase in the synthesis of this glycoprotein. This phenomenon offers a new model for studies on the TPA-induced regulation of gene expression.

Effect of Flow on Polymorphonuclear Leukocyte/Endothelial Cell Adhesion

By M.B. Lawrence, L.V. McIntire, and S.G. Eskin

The effect of flow on the adhesion of polymorphonuclear leukocytes (PMNL) to vascular endothelium was investigated using a parallel plate chamber with a well-defined flow field. Washed PMNL were perfused over a monolayer of primary human umbilical vein endothelial cells (HUVEC) pretreated with formyl-methionyl-leucyl-phenylalanine (FMLP, 1 × 10^{-7} mol/L) for five minutes. In other experiments HUVEC were pretreated with interleukin 1 (IL1, 2 U/mL) for four hours. PMNL adhesion to stimulated and control HUVEC was measured over a physiologic range of wall shear stresses. PMNL adhesion to nylon-coated surface was also studied. At a wall shear stress of 0.98 dynes/cm^2, 283 ± 37.3 PMNL/mm^2 (mean ± SEM) adhered to FMLP-treated HUVEC while 195 ± 20.3 PMNL/mm^2 adhered to control HUVEC. At 1.96 dynes/cm^2, 68 ± 14.1 PMNL/mm^2 adhered to FMLP-treated HUVEC and 42 ± 6.0 PMNL/mm^2 adhered to control HUVEC. At 3.92 dynes/cm^2, virtually no PMNL adherence was noted on either control or FMLP-treated HUVEC. On IL 1-treated HUVEC at 1.96 dynes/cm^2, 371 ± 25.8 PMNL/mm^2 adhered while 28 ± 2.9 PMNL/mm^2 adhered to control HUVEC. PMNL adhesion to IL 1-treated and control HUVEC dropped to 10.2 ± 3.8 and 6.8 ± 3.5 PMNL/mm^2, respectively, at 3.01 dynes/cm^2. The effect of flow on PMNL adhesion appears to be an important factor in determining the outcome of the PMNL/HUVEC adhesive interaction under these experimental conditions.

ONE OF THE FIRST responses of the immune system to injury or infection is the margination of leukocytes to the blood vessel wall. While the effects on leukocytes and endothelium of various inflammatory mediators have been extensively studied under quiescent conditions, little work has been done in characterizing the magnitude and significance of physical forces on the process of leukocyte attachment to the vessel wall. With the well-defined flow field that exists in a parallel-plate flow chamber, the importance of wall shear stress in the margination of polymorphonuclear leukocytes (PMNL) can be quantitated with respect to the effects of inflammatory mediators.

A number of recent investigations have pointed to an independent role for the endothelium in mediating PMNL adhesion. Chemotactic compounds such as leukotriene B_4, complement fragment C5a, and formyl-methionyl-leucyl-phenylalanine (FMLP) in nanomolar concentrations have been shown in several laboratories to increase adhesion of PMNL to endothelium, apparently by action on the endothelial cell (EC).[1-3] In one set of experiments we used the bacterial endotoxin analog, FMLP, to stimulate adhesion of PMNL to endothelium. Perhaps the most dramatic modulators of the adhesive interaction now being investigated are interleukin 1 (IL 1), tumor necrosis factor, thrombin, and lipopolysaccharide. These agents induce large increases in leukocyte adhesion to EC and, in the cases of IL 1 and thrombin, appear to act selectively on the EC.[4-8] In a related set of experiments we used monocyte-derived IL 1 to stimulate the endothelium and measured PMNL adhesion to endothelium under varying flow conditions. Our data show a strong flow dependence of PMNL adhesion to endothelium that modulates the previously reported chemical effects of FMLP and IL 1.

One of the more interesting characteristics of PMNL observed in various tissue preparations is their ability to roll along the endothelium of postcapillary venules for considerable distances before detaching, stopping, or emigrating through the blood vessel wall.[9-12] This report presents measurements of PMNL rolling velocities on control and FMLP-treated endothelium at varying wall shear stresses.

It has been postulated that granulocytes play a significant role in clinical complications resulting from extracorporeal blood flow, such as occurs during hemodialysis and cardiopulmonary bypass procedures.[13-15] The transient neutropenia and pulmonary sequestration of leukocytes associated with these procedures are thought to be caused by the activation of complement by blood-contacting surfaces.[13,15-17] We report data on PMNL adhesion to nylon surfaces after exposure to human plasma under conditions in which the likely mediator of the adhesive interaction is surface-bound complement fragment C3b.

MATERIALS AND METHODS

Endothelial cell cultures. Human umbilical vein endothelial cells (HUVEC) were harvested using collagenase digestion,[18] pooled, seeded onto glass slides (34 × 74 mm, Fisher Scientific Co, Springfield, NJ), and cultured in M199 (GIBCO Laboratories, New York) supplemented with 20% fetal calf serum (FCS, HyClone Laboratories Inc, Logan, UT), penicillin, streptomycin, and neomycin (PSN, 1% by volume, GIBCO). Cultures were used in experiments two to four days after reaching confluence.

Preparation of human PMNL. Venous blood from normal, healthy male donors was drawn into heparin (10 U/mL, final concentration). PMNL were isolated from heparinized whole blood by dextran sedimentation followed by hypotonic lysis of erythrocytes and centrifugation over Ficoll-Hypaque (FH).[19,20] The final pellet was resuspended in M199 at pH 7.4 to which 3.75 mg/mL of bovine

serum albumin (BSA, Sigma Chemical Co, St. Louis) was added (M199+BSA). PMNL were counted with a model ZBI Coulter Counter (Coulter Electronics Inc, Hialeah, FL) connected to a Coulter Channelyzer (Coulter Electronics) to determine the appropriate dilution ratio. Trypan blue exclusion showed greater than 96% viability.

Preparation of platelet-poor plasma. Venous blood was drawn into siliconized glass tubes containing heparin (10 U/mL, final concentration). After centrifugation at 400 × g for ten minutes, the supernatant was drawn off with a Pasteur pipet and centrifuged again at 1,000 × g for ten minutes. The resultant platelet-poor plasma (PPP) was transferred to a clean plastic tube.[20]

Experimental apparatus. To produce a well-defined wall shear stress, we used a parallel plate geometry for our flow chamber (Fig 1A).[21-24] One side of the chamber was a slide on which HUVEC were cultured. The other side was machined from polycarbonate. Once assembled these two flat surfaces were held approximately 250 μm apart by a Silastic rubber gasket (Dow Corning, Midland, MI). Because of the small gap-to-width ratio, the channel could be approximated over most of its surface as two infinite parallel plates. Under laminar flow conditions such as used in our experiments (Reynolds number < 2), the velocity profile is parabolic and the wall shear stress can be calculated utilizing the momentum balance for a Newtonian fluid.[24] As described in the following equation, the wall shear stress is equal to:

$$\tau = \frac{3\mu Q}{2a^2 b}$$

τ = Wall shear stress

μ = Coefficient of viscosity

Q = Volumetric flow rate

2a = Channel height

b = Channel width

A model 935 Harvard Apparatus syringe pump (South Natick, MA) was employed for flow control. Experiments were conducted at the following wall shear rates: 140 sec^{-1}, 280 sec^{-1}, 430 sec^{-1}, and 560 sec^{-1}. These shear rates, for a flowing tissue culture medium at 37°C, correspond respectively to wall shear stresses of 0.98, 1.96, 3.01, and 3.92 dynes/cm^2. This range of shear stresses is similar to those seen in venules and veins. PMNL/HUVEC interactions under these flow conditions were visualized directly using phase-contrast videomicroscopy and digital image processing (Fig 1).

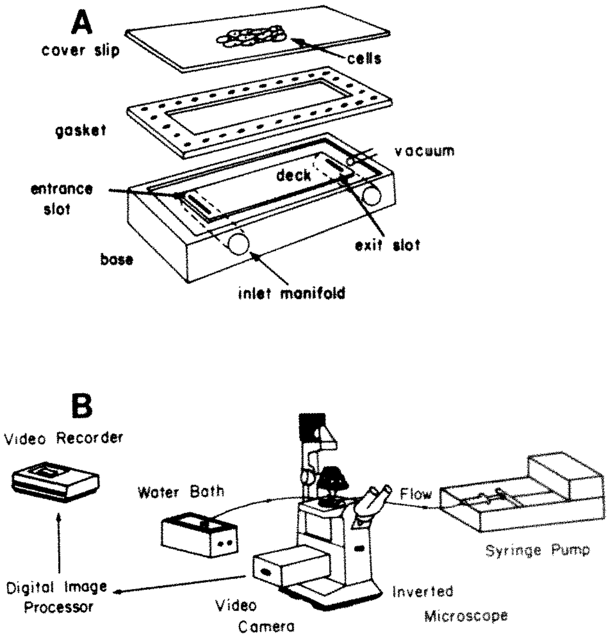

Fig 1. (A) Parallel plate flow chamber machined from transparent polycarbonate. The cover slip is covered with confluent HUVEC or coated with nylon. The silastic gasket separates the cover slip from the deck of the flow chamber and, when vacuum is applied, results in a channel gap of 250 μm. (B) The flow chamber is attached to the stage of the inverted-stage microscope. The syringe pump controls the flow and the water bath containing the PMNL cell suspension. An air-curtain incubator maintains the flow chamber, inlet tubing, and microscope stage at 37°C. The output of the video camera is recorded for later image processing and analysis.

Adhesion assay. The HUVEC covered slide was fitted onto the flow chamber and vacuum applied to hold it in place. The chamber was then rinsed with M199+BSA at 37°C for 30 minutes. The PMNL suspension was diluted with M199+BSA at 37°C to a cell concentration of 1,000 cells/μL and 30 minutes was allowed for the PMNL to stabilize. The PMNL suspension, the connecting tubing, and the microscope with flow chamber (Fig 2 B) were all maintained at 37°C by an air-curtain incubator (Laboratory Products, Boston; Model 279). Approximately 30 minutes after the PMNL were diluted, the HUVEC were exposed to 1 × 10^{-7} mol/L FMLP for five minutes and then rinsed for five minutes with M199+BSA. The PMNL suspension was then perfused through the flow chamber. Using a Hamamatsu video camera (Waltham, MA; Model C1012) mounted on a Nikon Diaphot-TMD inverted phase-contrast microscope (Garden City, NY), the experiments were videotaped. The number of PMNL attached to the HUVEC monolayer were counted after ten minutes of flow. The control consisted of the same experimental procedure without the incubation of the HUVEC with FMLP. For experiments involving IL 1 (Genzyme Inc., Boston), 100 μL of IL 1 (200 U/mL) in 0.5% BSA was introduced into the petri dish containing the HUVEC monolayer and diluted in the tissue culture medium to 2 U/mL. The HUVEC were incubated with the IL 1 for four hours preceding the experiment.[5] The control consisted of untreated HUVEC. The PMNL for each experiment were isolated from a single donor, and the HUVEC monolayers were from the same pooled seeding.

PMNL rolling velocities were measured by digital image processing (Perceptive Systems Inc., Houston; Model 327) of videotapes. The time interval used for these velocity measurements was 30 seconds to resolve PMNL velocities below 1 μm/sec. Accordingly, a stable adhesion was defined as one that lasted 30 seconds or longer. Normalized histograms of velocity distributions and the averages were determined from analyzing two to four frames of videotape separated by at least one minute in each experiment.

The same procedure for PMNL preparation was used with studies of PMNL adhesion to nylon. Glass slides were coated with Elvamide nylon (DuPont, Wilmington, DE) by solvent casting (MeOH, 1% solution). In some experiments the nylon surface was incubated with PPP for 20 minutes followed by a two-minute washout before the PMNL suspension was perfused through the chamber.

Statistical analysis. The variation in adhesion ratios was analyzed using a one-tailed *t* test for paired data since the control, FMLP-treated and IL 1-treated HUVEC, were from the same population of pooled cells, and the washed PMNL used in the experiment were from the same donor. Ratios of the means of PMNL rolling velocities on FMLP-treated HUVEC and controls as well as ratios of the means at two shear stresses were compared using a two-tailed *t* test. A two-tailed *t* test was also used to compare PMNL rolling velocity distributions. Error bars on all histograms represent the SEM.

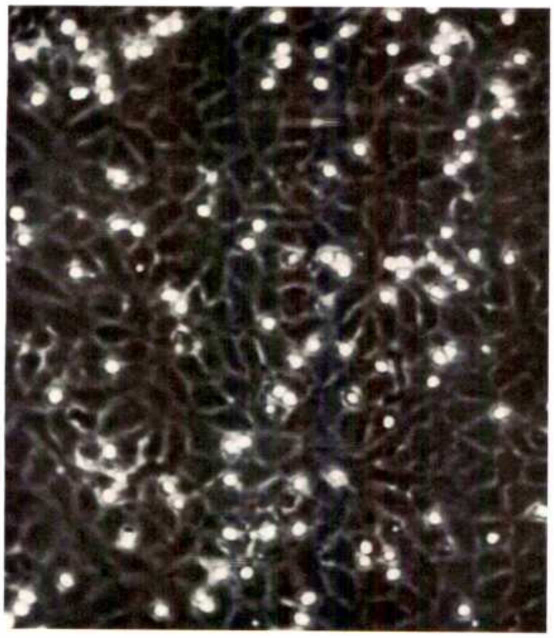

Fig 2. PMNL adherent to FMLP-treated HUVEC monolayer under flow taken from digitized frame of videotape (magnification 20 × objective). The large white dots are PMNL adhering to the HUVEC monolayer (dark background with barely visible HUVEC outlines). PMNL counts in the field of view are normalized to PMNL/mm^2. Wall shear stress = 0.98 dynes/cm^2. (Figure reduced to 65% of original size.)

RESULTS

In paired experiments at 0.98 dynes/cm^2 wall shear stress, the ratio of PMNL adhesion to FMLP-treated HUVEC *v* control HUVEC was 1.45 ($P < .01$, n = 9, Fig 3). At this wall shear stress 283 ± 37.3 PMNL/mm^2 (mean ± SEM) adhered to FMLP-treated HUVEC and 195 ± 20.3 PMNL/mm^2 adhered to control HUVEC after ten minutes of flow. At 1.96 dynes/cm^2 wall shear stress, the ratio of PMNL adhesion to FMLP-treated HUVEC *v* control HUVEC was 1.58 ($P < .025$, n = 8). At this wall stress 68 ± 14.1 PMNL/mm^2 adhered to FMLP-treated HUVEC and 42 ± 6.0 PMNL/mm^2 adhered to control HUVEC after ten minutes of flow. At 3.92 dynes/cm^2 wall shear stress, virtually no cell adherence was noted on either control or FMLP-treated HUVEC (<1 cell/mm^2, n = 3), although there were many transient white cell/endothelial cell interactions.

In paired experiments at 1.96 dynes/cm^2 wall shear stress, 371 ± 25.8 PMNL/mm^2 adhered to IL 1-treated HUVEC and 28 ± 2.9 PMNL/mm^2 adhered to control HUVEC, resulting in an adhesion ratio of 13.8 ± 1.2 ($P < .01$, n = 5, Fig 4). At 3.01 dynes/cm^2 wall shear stress, 10.2 ± 3.8 PMNL/mm^2 adhered to IL 1-treated HUVEC and 6.8 ± 3.5 PMNL/mm^2 adhered to control HUVEC, giving an adhesion ratio of 1.65 ± 0.25 ($P < .05$, n = 5).

At 0.98 dynes/cm^2 wall shear stress, 9.7 ± 3.8 PMNL/mm^2 adhered to the nylon surface while on nylon pretreated with PPP, 77 ± 21.7 PMNL/mm^2 adhered, giving an adhesion ratio of 7.9:1 ($P < .01$, n = 4, Fig 5). There was almost no adhesion (<1 cell/mm^2, n = 3) of PMNL to untreated nylon at 1.96 dynes/cm^2 (data not shown).

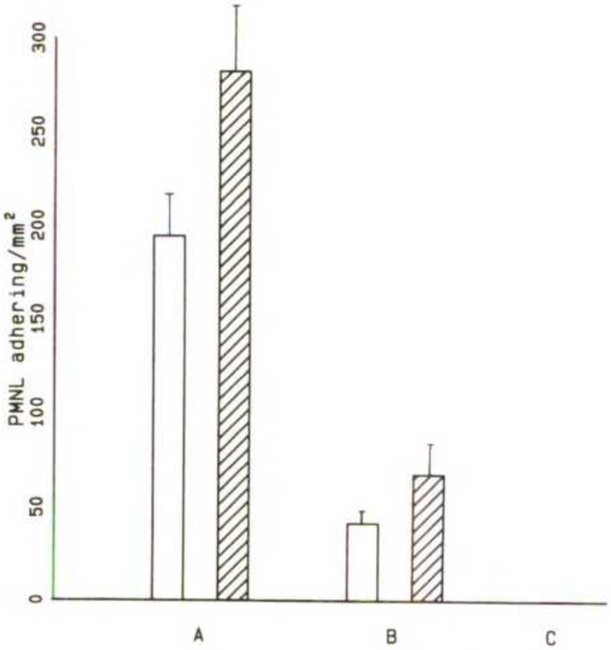

Fig 3. Effect of flow and FMLP-treatment of HUVEC on PMNL adhesion. Experiments performed at wall shear stresses of 0.98 dynes/cm^2 (A, 140 sec^{-1}), 1.96 dynes/cm^2 (B, 280 sec^{-1}), and 3.92 dynes/cm^2 (C, 560 sec^{-1}). PMNL were suspended in M199+BSA (1,000 cells/μL) at 37°C. FMLP-treated HUVEC (1 × 10^{-7} mol/L, five minutes), cross-hatched bars; control HUVEC, open bars. Error bars represent SEM.

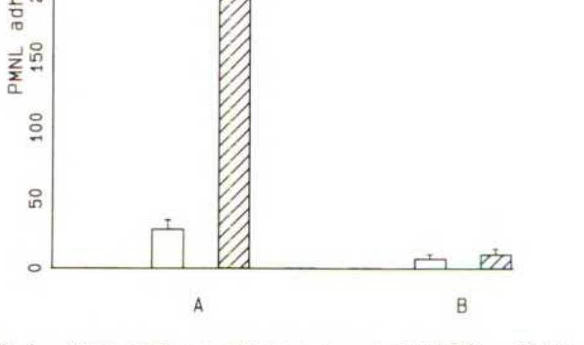

Fig 4. Effect of flow and IL 1 treatment of HUVEC on PMNL adhesion. Experiments performed at wall shear stresses of 1.96 dynes/cm^2 (A, 280 sec^{-1}) and 3.01 dynes/cm^2 (B, 430 sec^{-1}). PMNL were suspended in M199+BSA (1,000 cells/μL) at 37°C. IL 1-treated HUVEC (2 U/mL, four hours), cross-hatched bars; control HUVEC, open bars. Error bars represent SEM.

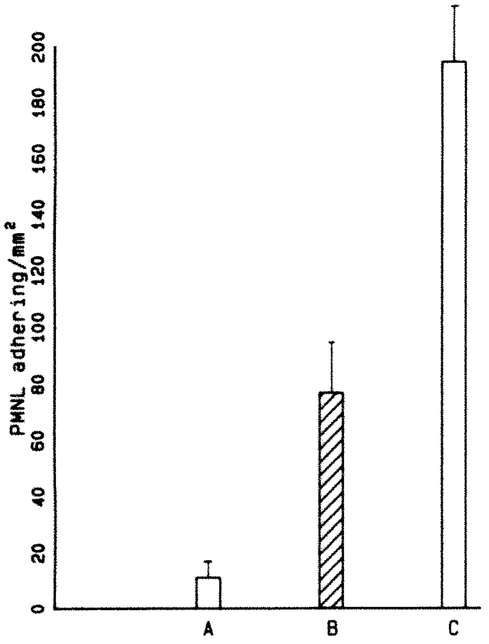

Fig 5. PMNL adhesion to nylon-coated surface under flow (0.98 dynes/cm², 140 sec⁻¹). PMNL were suspended in M199+BSA (1,000 cells/μL) at 37°C. PMNL/mm² adhering to untreated nylon surface (A), PMNL/mm² adhering to nylon preincubated with PPP for 20 minutes (B), PMNL/mm² adherent to control HUVEC (C). Error bars represent SEM.

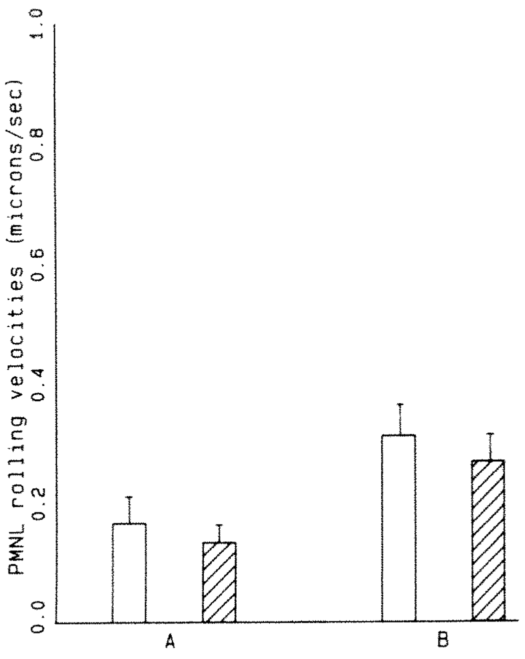

Fig 6. Effect of flow and FMLP treatment of HUVEC on the mean rolling velocities of PMNL. Experiments performed at wall shear stresses of 0.98 dynes/cm² (A, 140 sec⁻¹) and 1.96 dynes/cm² (B, 280 sec⁻¹). FMLP-treated HUVEC, cross-hatched bars; control HUVEC, open bars. Error bars represent SEM.

At a wall shear stress of 0.98 dynes/cm², PMNL that were attached to control HUVEC had an average rolling velocity of 0.166 ± 0.046 μm/sec; and PMNL attached to FMLP-treated HUVEC had an average rolling velocity of 0.134 ± 0.026 μm/sec (n = 3, Fig 6). The difference between these means due to FMLP treatment of the HUVEC monolayer was not significant ($P > .4$). At a wall shear stress of 1.96 dynes/cm², PMNL attached to control HUVEC had an average rolling velocity of 0.313 ± 0.054 μm/sec, and PMNL attached to FMLP-treated HUVEC had an average rolling velocity of 0.269 ± 0.047 μm/sec (n = 5). The difference between these means due to FMLP treatment of the HUVEC monolayer was also not significant ($P > .4$). The ratio of PMNL rolling velocities at 1.96 and 0.98 dynes/cm² wall shear stress was 1.94 ($P < .02$).

Between 20% and 90% of the PMNL with stable adhesions to the HUVEC monolayer rolled downstream. At 0.98 dynes/cm², less than 1% of the PMNL rolled faster than 1 μm/sec (Fig 7), while at 1.96 dynes/cm², approximately 5% of the PMNL rolled faster than 1 μm/sec (Fig 8). Differences in velocity distributions due to FMLP treatment of the

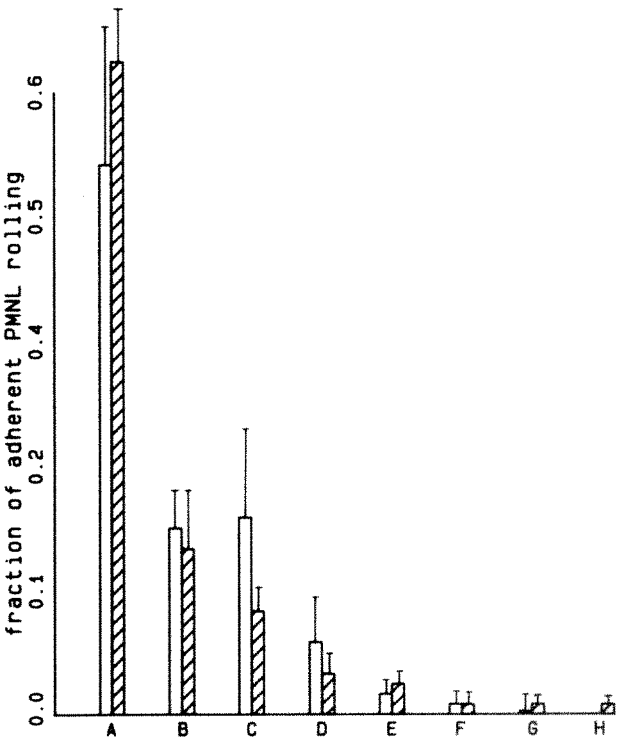

Fig 7. Distribution of PMNL rolling velocities at 0.98 dynes/cm². FMLP-treated HUVEC, cross-hatched bars; control HUVEC, open bars. Each pair of bars represents the fraction of adherent PMNL with rolling velocities ranging from 0.0 to 0.13 μm/sec (A), 0.13 to 0.26 μm/sec (B), 0.26 to 0.39 μm/sec (C), 0.39 to 0.52 μm/sec (D), 0.52 to 0.65 μm/sec (E), 0.65 to 0.78 μm/sec (F), 0.78 to 0.91 μm/sec (G), and 0.91 to 1.04 μm/sec (H). To generate a representative velocity distribution for each experiment, the normalized velocity distributions from two to four image frames of videotapes (separated in each case by at least one minute) were averaged. Histograms from experiments under the same conditions were again averaged to create a final normalized velocity distribution. Error bars represent SEM.

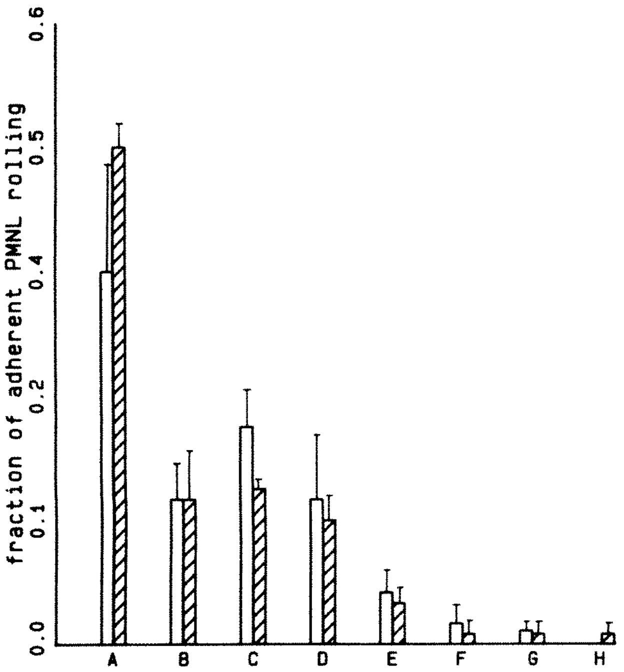

Fig 8. Distribution of PMNL rolling velocities at 1.96 dynes/cm^2. FMLP-treated HUVEC, cross-hatched bars; control HUVEC, open bars. Each pair of bars represents the fraction of adherent PMNL with rolling velocities ranging from 0.0 to 0.13 μm/sec (A), 0.13 to 0.26 μm/sec (B), 0.26 to 0.39 μm/sec (C), 0.39 to 0.52 μm/sec (D), 0.52 to 0.65 μm/sec (E), 0.65 to 0.78 μm/sec (F), 0.78 to 0.91 μm/sec (G), and 0.91 to 1.04 μm/sec (H). To generate a representative velocity distribution for each experiment, the normalized velocity distribution from two to four image frames of videotape (separated in each case by at least one minute) were averaged. Histograms from experiments under the same conditions were again averaged to create a final normalized velocity distribution. Error bars represent SEM.

HUVEC monolayer were not significant at the two flow conditions examined, although a broader distribution of rolling velocities was observed at 1.96 dynes/cm^2.

In experiments with nylon surfaces, we observed no PMNL downstream rolling, although PMNL in the plane of focus next to the nylon surface had velocities that ranged from 300 to 600 μm/sec. Extensive spreading of PMNL attached to the PPP-incubated nylon surface was observed.

DISCUSSION

From our experiments fluid drag forces appear to have a major impact on the number of PMNL adhering to endothelium. Doubling the wall shear stress from approximately 1 to 2 dynes/cm^2 reduced the number of adherent PMNL by more than a factor of four on both control and FMLP-treated endothelium. Doubling the wall shear stress again from approximately 2 to 4 dynes/cm^2 reduced adhesion to virtually zero. On IL 1-treated endothelium, the level of adhesion was 13-fold more than on controls at 2 dynes/cm^2, as was expected from earlier results of static experiments on PMNL/EC adhesion.[5] Increasing the wall shear stress to approximately 3 dynes/cm^2 on the IL 1-treated HUVEC dropped both the adhesion ratio and the absolute number of adherent PMNL dramatically. This large decrease in the level of PMNL adhesion, even on highly stimulated endothelium, over a small range of wall shear stresses is in accord with Lackie's proposal that the PMNL/EC adhesive force is delicately balanced with the shear force due to fluid drag.[25,26]

The wall shear rates examined in these experiments are close to those estimated for the venules and large blood vessels but are lower than those estimated for the capillary bed where there is normally little PMNL adhesion.[27] In vivo, the abrupt drop in shear forces found in the transition from capillaries to venules coincides with the location of the bulk of PMNL adhesion in the microcirculation.[26] A qualitatively similar pattern can be seen in our model vessel data using dilute suspensions of PMNL. Our data suggest that PMNL adhesion to endothelium (even activated endothelium) can occur only after shear forces have dropped below a threshold level and may explain in part why PMNL normally adhere in venules and not in capillaries.

By eliminating complex geometry and the resultant complex fluid mechanics, the flow system described simplifies the type of forces a PMNL experiences and permits a direct correlation of wall shear stress with the level of PMNL/EC adhesion. In our experiments a dilute, washed PMNL suspension was used so that any influence of platelets or erythrocytes would be eliminated. However, there has been some recent evidence that in plasma PMNL adhesion to EC is reduced.[28] Pretreatment of the PMNL with FMLP was not done, as the purpose of this work was to evaluate the role of the endothelial cell substrate on PMNL adhesion. Preactivation of PMNL would probably lead to very different levels of leukocyte adhesion to HUVEC. It has been shown that FMLP causes a 20-minute aggregation response in PMNL, so the incubation times for endothelial cells were selected accordingly.[20] Tonneson et al[29] have reported that exposure of endothelial cell monolayers to FMLP at a comparable concentration for periods of time ranging from 15 minutes to 4 hours did not increase PMNL adhesion to the monolayer. Thus, the small increases in adhesion seen in our work (Fig 3) and that of others may be due to some PMNL activation by low levels of residual FMLP.[1,3]

The number of PMNL sticking to nylon was very low when compared with the number of PMNL that adhered to endothelium at a wall shear stress of 0.98 dynes/cm^2. When the wall stress was doubled, we observed no PMNL adhering to the untreated nylon surface. The contact of the nylon-coated flow chamber wall with PPP, as would occur if blood were in contact with a similar type of foreign surface, dramatically increased the adhesion of PMNL[30] (Fig 5). PMNL have receptors for the complement fragments C3b and C3bi for effectively attaching to opsonized surfaces and facilitating the phagocytosis of bacteria.[31,32] However, when nylon activates the C3 convertase enzyme, the C3b and C3bi fragments formed probably bind to nylon's polysaccharide-like surface, possibly forming an "opsonized" surface for the PMNL to attach to.

An unattached PMNL near the wall of our flow chamber would be moving at a velocity of several hundred μm/sec if there were no interactions with the endothelial cell monolayer, as was the case of PMNL near the nylon surface. In contrast, the mean rolling velocities of PMNL we report on endothelium are considerably less than 1 μm/sec, which indicates that there is a strong adhesive interaction occurring. In addition, our data show a strong dependence of mean rolling velocity on wall shear stress. The mean rolling velocity of PMNL subjected to a wall shear stress of 1.96 dynes/cm^2 was approximately double the mean rolling velocity of PMNL subjected to 0.98 dynes/cm^2.

Atherton and Born[10] have reported that in vivo granulocyte rolling velocities exhibit a strong flow dependence. Unexpectedly, there was no significant difference in average PMNL rolling velocities due to FMLP-pretreatment of the HUVEC at either flow rate examined. With both FMLP and control experiments, the effect of increased wall shear stress was to broaden the distribution of velocities of rolling PMNL at the higher flow rate as well as to raise the mean rolling velocity of attached cells. The velocity distributions in all the experiments analyzed were similar and show consistently that 20% to 90% of the attached PMNL were rolling downstream. Since a large fraction of PMNL roll downstream due to flow, it is possible that this intermediate level of adhesion is a property of leukocytes that allows them to marginate from the bulk flow in the circulation yet still retain some mobility along the vessel wall. In our experiments with PMNL adhering to nylon, we observed what appeared to be cell spreading but no rolling PMNL, which suggests the interaction is of a different nature than the PMNL/HUVEC adhesive interaction.

Little is known about the type and strength of the bonds formed between PMNL and EC or the actual forces on the interface that determine whether or not the PMNL will adhere.[9,11] Employing a centrifugation assay that determined the force needed to separate PMNL from an endothelial cell monolayer after coincubation of the two cell types, Charo et al[33] have reported that FMLP and C5a increase the strength of PMNL adhesion to endothelium. A stronger adhesive interaction with the stimulated endothelium implies that rolling velocities would be lower, and PMNL flowing near the EC monolayer would be more readily arrested. However, only slight differences were observed between PMNL rolling velocities on FMLP-treated and control endothelium. Additionally, our data indicated the threshold shear stresses for PMNL adhesion to untreated, FMLP-treated, and IL 1-treated HUVEC were very close to each other. The pattern of PMNL adhesion to HUVEC at different shear stresses suggests that, while there were many more adhesive sites on IL 1 and FMLP-treated endothelium, the adhesive bonds formed were not necessarily stronger than on untreated HUVEC.

Even though static conditions in the blood rarely occur, most studies of leukocyte adhesion have been conducted in systems without controlled flow effects. These studies have revealed much about the biochemical interactions involved in leukocyte adhesion to endothelium but say little about the relative importance of different forms of activation under the wide range of physiologic conditions PMNL encounter in vivo. Our data, showing that slight changes in wall shear stresses can cause large changes in PMNL adhesion to both stimulated and unstimulated HUVEC, suggest that the local control of blood flow—perhaps by vessel dilation—may be as significant as the presence of inflammatory mediators in determining where the arrest of leukocytes occurs.

Phorbol Ester Induces Interleukin-2 Receptor on the Cell Surface of Precursor Thymocyte Leukemia With no Rearrangement of T Cell Receptor β and γ Genes

By Yasuo Morishima, Yoshihisa Morishita, Koichi Adachi, Mitsune Tanimoto, Ryuzo Ohno, and Hidehiko Saito

The early event of thymocyte maturation has been analyzed using acute lymphoblastic leukemia (ALL) cells. A group of ALL cells whose cell surface phenotype was CD2 (SRBC receptor) negative and CD7 (T cell antigen) positive has been considered as precursor thymocyte ALL (pre-T-ALL). No rearrangements of the T cell receptor β-gene (TCR β) and γ-gene (TCR γ) were found in three of four pre-T-ALL patients. Stimulation of these pre-T-ALL cells with 12-0-tetradecanoylphorbol-13-acetate (TPA) induced only CD25 (Tac) antigen but no other T cell antigens. These findings suggest that the activation pathway of interleukin 2 (IL-2) receptor already exists in the most immature precursor thymocytes. Pre-T-ALL cells from the fourth patients showed the expression of CD3 antigen, and both TCR β and TCR γ rearrangement. TPA induced the differentiation of the more mature pre-T-ALL cells of this case in vitro, and not only CD25 (Tac) antigen but also CD4 and CD8 antigens appeared on the cell surface. The low affinity binding of ^{125}I-IL-2 to TPA-stimulated leukemia cells was observed in the three cases of pre-T-ALL tested, and the addition of recombinant IL-2 to TPA-stimulated cells showed no effect on cell proliferation.

IT HAS RECENTLY become evident that the process of T cell differentiation from immature thymocytes to mature functional T cells accompanies the rearrangement of T cell receptor (TCR) genes and the sequential changes of T cell surface differentiation antigens.[1-4] Precursor T cells that migrate to thymus will acquire the potential to respond to exogenous stimulation during the activation process of TCR genes. These early events of T cell maturation in the thymus have been analyzed using acute lymphoblastic leukemia (ALL) cells, because some type of leukemia cells is considered to be a clonal expansion of thymocytes at certain stages of T cell differentiation.[5,6]

A group of ALL that is supposed to arise from immature precursor thymocytes has been identified by several investigators.[7-10] These ALL cells have the characteristic cell surface phenotype of CD7 positive and CD2 (sheep RBC [SRBC] receptor) negative. It was also reported that some of these ALL cells showed no TCR β gene rearrangement.[11,12]

In order to investigate the earliest event in the thymus, we selected CD7 (+) CD2 (−) ALL cells, and analyzed not only the cell surface antigens but also TCR β and γ gene rearrangements. Furthermore, these leukemia cells were stimulated with phorbol diester, 12-0-tetradeconoylphorbor-13-acetate (TPA), and the changes of T cell differentiation antigens were analyzed.

MATERIALS AND METHODS

Leukemia sample. Four patients with acute leukemia with CD7 positive and CD2 negative were analyzed. Case no. 1 was an 11-year-old boy with thymoma, splenomegaly, and hepatomegaly at diagnosis. Peripheral blood WBC count (PB-WBC) was 37,900/mm^3 with 90% leukemia cells, and >92% of bone marrow nucleated cells (BM-NC) were leukemia cells morphologically at diagnosis. Case no. 2 was a 23-year-old man without thymoma. PB-WBC was 22,000/mm^3 with 90% leukemia cells, and BM-NC contained 96% leukemia cells. Case no. 3 was a 9-year-old boy with thymoma. PB-WBC was 26,000/mm^3 with 80% leukemia cells and BM-NC contained 94% leukemia cells. Case no. 4 was a 19-year-old man without thymoma and with splenomegaly and hepatomegaly. PB-WBC was 300,000/mm^3 with 94% leukemia cells. BM-NC contained 97% leukemia cells. One patient with CD2 and CD7 positive T-ALL was also analyzed. All leukemia samples were obtained from bone marrow at diagnosis. The mononuclear cells were separated by Ficoll-Hypaque gradient method, and stored at −180°C in liquid nitrogen. After thawing, all of the samples had >90% viability and >95% leukemia cells. The Giemsa staining of these leukemia cells showed the morphological characteristics of ALL, and both peroxidase staining and esterase staining were negative in all cases.

Monoclonal antibody. Monoclonal antibodies (MoAbs) used for the analysis of cell surface antigens were NA1/34 (CD1), 9.6 and Leu 5b (CD2), UCHT-1 and T3 (CD3), T4 (CD4), UCHT-2 (CD5), 12.1 (CD6), 4A (CD7), Leu 2a (CD8), and T1A (CD25). CD number is the specificity of antigens according to the nomenclature of the International Workshop on Human Leukocyte Differentiation Antigens,[13] and all of these MoAbs were obtained from the second and the third workshops. MoAb 35.1 (CD2) for T cell purging was kindly provided by Dr J.A. Hansen, Fred Hutchinson Cancer Research Center, Seattle, and MoAb 4A (CD7) were produced and analyzed by Y. Morishima.[8]

Immunofluorescent test. The indirect immunofluorescent test (IF) was performed with saturating condition of MoAbs. Five × 10^5 cells were incubated with 50 μL of MoAbs at 4°C for 30 minutes. Excess antibody was removed by washing twice in phosphate-buffered saline (PBS) supplemented with 0.4% bovine serum albumin and 0.02% sodium azide. Then 50 μL of FITC-conjugated F(ab')$_2$ fragment of goat anti-mouse IgGM (1:40 dilution) (Tago, Burlingame, CA) was added, and the mixture was incubated for another 30 minutes at 4°C. The cells were further washed three times and the percentage of fluorescence positive cells was counted using flow cytometry (FACS analyzer, Beckton Dickinson, Mountain View, CA). Normal mouse serum was used as negative control for background fluorescence. The fluorescence positive cells of the samples were counted when the base line of negative control was set to be positive in <5% of cells.

Stimulation of leukemia cells with TPA. In order to remove the small amount of contaminated PB T cells in leukemia samples, 1 ×

10^7 of precursor thymocyte ALL (pre-T-ALL) cell sample was incubated with 1 mL of MoAb 35.1 (100 times dilution of ascitis) for 30 minutes at 4°C, and baby rabbit complement (Pel-Freez, Rogers, AR) was then added at the final concentration of 50% (vol/vol). After 60 minutes of incubation at 37°C, the cells were washed twice, and used for the incubation with TPA (Paesel GmbH & Co, Frankfurt, West Germany). One × 10^6/mL of T cell-depleted leukemia cells in culture medium (RPMI 1640 with 10% fetal calf serum, penicillin and streptomycin) were incubated with 1×10^{-7} mol/L TPA at 37°C in a humidified 5% CO_2 incubator. After 2, 6, 12, 24, and 72 hours, the cells were harvested, and the changes of cell surface antigens on these stimulated cells were analyzed by IF test.

In another experiment, the proliferation of pre-T ALL cells by TPA with or without interleukin-2 (IL-2) was tested in triplicate. Two × 10^5/well of T cell-depleted leukemia cells were incubated with or without 1×10^{-7} mol/L TPA using a 96-well flat microplate at 37°C in a humidified 5% CO_2 incubator for 24 hours, and then recombinant IL-2, which was kindly provided from Takeda Pharmaceutical Co, Osaka, Japan, was added to the wells at a final concentration of 0.1 μg/mL. After two- and five-day incubation, 1 μCi of ^{3}H-thymidine (New England Nuclear, Boston) was added to the well, and the cells were cultured for another 15 hours. The incorporation of ^{3}H-thymidine into DNA was measured with liquid scintillation counter.

Radiolabeled IL-2 binding assay. Before determining the level of binding, cells were incubated twice for one hour at 37°C in 50 mL RPMI 1640 in order to remove endogeneous IL-2. After washing, the cells were resuspended in RPMI 1640 supplemented with 25 mmol/L Hepes (pH 7.3) and 10 mg/mL BSA (RPMI-BSA). Serial dilutions of recombinant human ^{125}I-IL-2 (32.6 μCi/ng, New Research Products, Boston) were incubated at 37°C for ten minutes with 5×10^5 cells in a total volume of 100 μL RPMI-BSA using a 96-well round bottomed microtiter plate. After incubation, the cells were centrifuged through a layer of silicon oil/paraffin oil mixture in 400 μL polyethylene tubes (9,000 g for 90 seconds) according to the method of Robb et al.[14] The supernatant from the first wash was counted to determine the level of unbound IL-2. After washing once, the tops of the tubes containing the cell pellet were cut off and were counted to determine the level of bound IL-2. The dissociation constant (kd) and the number of IL-2 receptor binding sites were calculated from Scatchard plot analyses.

Gene rearrangement analysis. High-molecular-weight DNA was prepared from frozen samples by standard sodium sulfate-proteinase K method followed by phenol extraction and ethanol precipitation. These DNA samples (15 μg) were digested with restriction enzymes *Bam*HI, *Eco*RI or *Hind*III (Boehringer Manheim GmbH, West Germany) and were size-separated by 0.7% agarose gel electrophoresis and were transferred by Southern's method[15] to nitrocellulose papers (Schleicher & Schuell, Keene, NH). These papers were then hybridized with nick-translated ^{32}P-labeled DNA probes at 42°C for 16 hours. Blots were washed at high stringency and were exposed against Kodak AR-5 film (Kodak, Rochester, New York).

Three probes used in this study were JH (1.2 Kb *Hind*III fragment of mouse heavy chain J region), which was kindly provided by Dr J. Ravetti, Memorial Sloan Kettering Cancer Research Institute, New York; C (0.7 Kb *Eco*RI fragment of mouse TCR β chain constant region), which was purchased from Oncor Co, Gaithersburg, MD; and Tγ5 (1.0 Kb *Eco*RI fragment of human TCR γ chain constant region), which was generously provided by Dr D. R. Littman, University of California.

RESULTS

Characterization of T cell differentiation antigens and TCR β, TCR γ, and JH gene rearrangement in pre-T-ALL cells. Four cases of pre-T-ALL with cell surface phenotypes of CD2 (−) and CD7 (+), and one case of T-ALL (case no. 5) were selected for analysis. All of four pre-T-ALL cells expressed another T cell antigen CD5, while only one case (case no. 4) expressed CD3 antigen, and no other T cell antigens (CD1, CD2, CD4, CD6, CD8) including Tac antigen (CD25) were detected on the cell surface of these 4 pre-T-ALL cells (Table 1).

Southern blot analysis of TCR β, TCR γ, and Ig heavy chain gene rearrangement demonstrated that no rearrangements of these three genes occurred in cases no. 1, 2, and 3, while TCR β and TCR γ gene had rearranged in cases no. 4 and 5 (Table 1). Restriction fragment patterns of TCR γ gene were shown in Fig 1. *Bam*HI digestion of germ line DNA (Fig 1, lane 7) resulted in 17-, 3.3-kb bands containing Cγ1 sequences and 12-, 5-, 4-kb bands containing Jγ2 to Cγ2 sequences, whereas *Eco*RI digestion of the DNA resulted in 5.0-, 2.2-kb bands containing Cγ1 and 6.9-, 1.8-kb bands containing Cγ2 regions. Distinct bands of 1.3 kb in *Eco*RI digests seem to represent fragments containing Cγ1 or Cγ2 sequences according to the restriction map of human genomic TCR γ chain gene (Dan R. Littman, personal communication). Three of four pre-T-ALL (cases no. 1, 2, and 3; Fig 1: lanes 2, 5, and 4, respectively) showed germ line pattern in both *Bam*HI and *Eco*RI digests, while case no. 4 of pre-T-ALL (lane 3) and case no. 5 of T-ALL (lane 6) exhibited the rearrangement of TCR γ gene involving Cγ2 region with the deletion of Cγ1 region.

Induction of Tac antigen (CD25) on pre-T-ALL cells by TPA stimulation. Pre-T-ALL cells were cultured with or without TPA, and the expression of various T cell antigens on

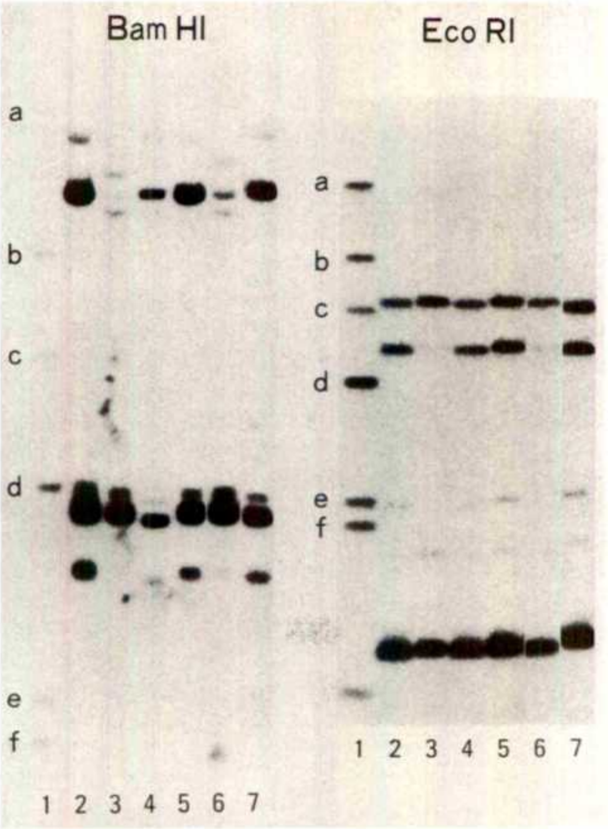

Fig 1. TCR γ gene rearrangement of pre–T-ALL cells. Southern blot analysis using a probe for TCR constant region was performed. (a-f) the size of standard fragment of DNA *Hind*III (a, 23 kb; b, 9.4 kb; c, 6.6 kb; d, 4.2 kb; e, 2.3 kb; f, 2.0 kb). Lane 1, standard; lane 2, case no. 1 (pre–T-ALL); lane 3, case no. 4 (pre–T-ALL); lane 4, case no. 3 (pre–T-ALL); lane 5, case no. 2 (pre–T-ALL); lane 6, case no. 5 (T-ALL); and lane 7, normal granulocytes.

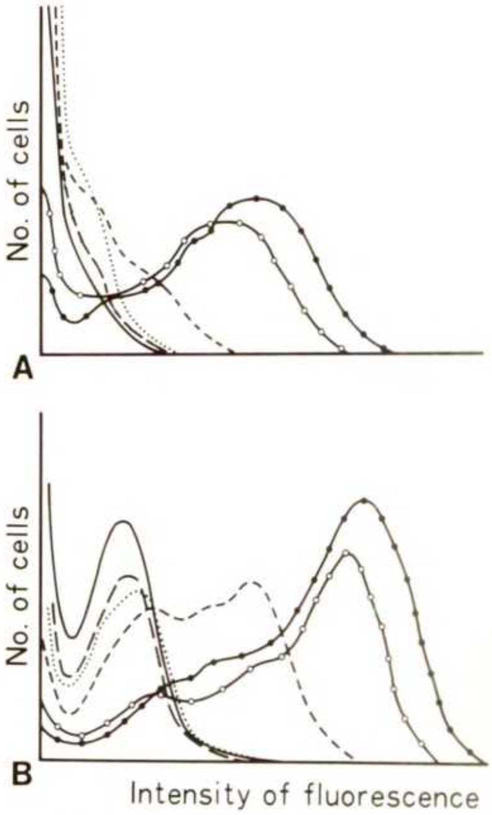

Fig 2. Changes of the expression of Tac antigen on pre–T-ALL cells by the stimulation of TPA. Pre–T-ALL cells were incubated with TPA, and indirect immunofluorescent test was performed using MoAb T1A (anti Tac, CD25), and analyzed by cytofluorography. The following lines indicate the incubation time: Before incubation, (—); after two hours, (– – –); six hours, (------); 12 hours (- - - - - -); 24 hours, (–○–○–); 72 hours (–●–●–).

these stimulated cells was analyzed by IF assay using fluorocytometry. The results after two-day culture were shown in Table 2. All four cases expressed Tac antigen (CD25) after TPA stimulation, while incubation without TPA for two days could not induce Tac antigen in all cases. The time course of the appearance of Tac antigen by TPA stimulation was analyzed in cases no. 1 and 4 (Fig 2). Tac antigen began to appear after 12 hours of incubation, and reached maximum expression after 24 hours in both cases. Increase in cell number during the culture was not observed, and the viability of the sample was kept at >80%.

Changes of the other T cell antigens on pre–T-ALL cells by TPA stimulation. As shown in Table 2, no CD2 antigen (SRBC receptor) appeared, and no CD1 or CD6 antigen was induced in all four cases (data not shown). Both CD7 antigen and CD5 antigen, which had been already expressed on the unstimulated cells, showed a tendency to decrease the per-

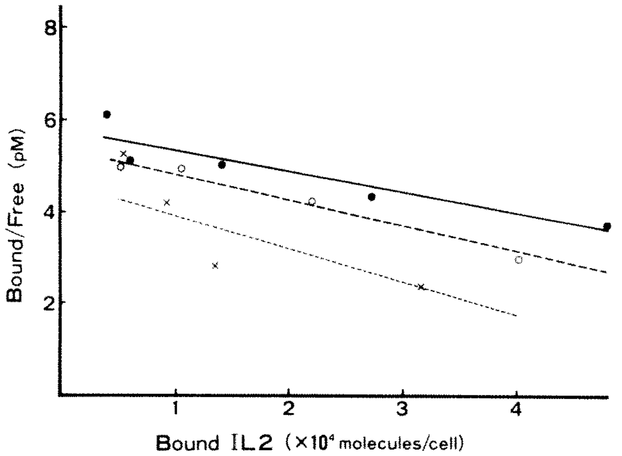

Fig 3. A Scatchard plot for the binding of ^{125}I-IL-2 to TPA-stimulated (24 hours) pre-T-ALL cells. Five × 10^5 cells were incubated with several dilutions of ^{125}I-IL-2. The data were corrected for nonsaturable binding by measuring the residual binding in the presence of 100-fold unlabeled IL-2 in selected tubes to give specific binding. Case no. 1, (●——●); case no. 2, (O----O); case no. 3, (x-----x).

centage and intensity of IF positive cells during the in vitro incubation with and without TPA. Interestingly, case no. 4 leukemia cells expressed CD4 and CD8 antigens by the stimulation with TPA for two days.

^{125}I-IL-2 binding analysis of TPA-incubated leukemia cells. For the further evaluation of the functional state of IL-2 receptor, which had been detected immunologically by anti-Tac antibody, various concentrations of ^{125}I-IL-2 were incubated with leukemia cells that had been treated with 1×10^{-7} mol/L TPA for 24 hours. The results of Scatchard plot analysis of such binding experiments confirmed that at IL-2 concentration of >1 nmol/L, saturable binding observed in both CD3(+) and CD3(−) pre-T-ALL cells after the stimulation with TPA (Fig 3). Low-affinity binding sites of CD3(−) pre-T-ALL were calculated to be 1.21×10^5/cell with kd 3.1 nmol/L (case no. 1) and 1.09×10^5/cell with kd 12.9 nmol/L (case no. 2), and those of CD3(+) pre-T-ALL (case no. 4) were 5.86×10^4/cell with kd 14.1 nmol/L.

Proliferative responses of pre-T-ALL cells to TPA and IL-2. In order to investigate whether pre-T-ALL cells that express IL-2 receptor by TPA stimulation respond to exogeneous IL-2, PB-T cell-depleted leukemia cells were cultured with TPA in the presence or absence of recombinant IL-2, and the proliferative responses of leukemia cells were measured by the uptake of ^{3}H-thymidine in case no. 1 and case no. 4 (Table 3). The increase of ^{3}H-thymidine uptake was observed in case no. 4 with the stimulation of TPA alone, and a maximum uptake was observed at four days of incubation. On the other hand, the uptake with the stimulation of TPA remained at the same level as that without TPA in case no. 1. When exogeneous IL-2 was added to the TPA-stimulated leukemia cells, no additional increase of ^{3}H-thymidine uptake was observed in either case tested.

DISCUSSION

ALL with the cell surface antigens of negative SRBC receptor (CD2) and positive CD7 T cell antigen has been classified as one category of ALL by Haynes using MoAb 3A1 (CD7),[7,16] Morishima et al using MoAb 4A (CD7),[8] Link et al using MoAb 4H9 (CD7),[9] and Vodinelich et al using MoAb WT1 (CD7).[10] There is evidence that these leukemia cells originate from precursor thymocytes as follows: (1) Many of these leukemia cells express not only CD7 T cell antigen, but also CD5 T cell antigen; (2) many of these leukemia patients have thymoma at diagnosis; and (3) these leukemia cells do not express Leu 7 and Leu 11 antigens, which are the marker of natural killer cells (data not shown). Furthermore, Tsuge et al's finding[17] that SRBC receptor-negative normal thymocytes do express CD7 antigen also supports the origin of this leukemia.

In the present study, three precursor thymocyte (pre-T) ALL cases, which expressed no T cell antigens except CD7 and CD5, showed no TCR β gene rearrangement. These data are in good agreement with Pittaluga et al,[11] and Suzuki et al[12] reports that CD7 expression precedes TCR β gene rearrangement in precursor T lymphoblastic neoplasms. As indicated by Pittaluga et al,[18] our three pre-T-ALL cases with no rearrangement of TCR β gene also showed no rearrangement of TCR γ gene. Therefore, these three pre-T-ALL had most immature characteristics of precursor thymocytes in which both TCR β and γ genes are kept in germ line configurations. Our preliminary data showed that all of three T-ALL cases and only one of four adult T cell leukemia cases also showed TCR γ gene rearrangement (data not shown). Griesser et al also reported that B cell lymphoma cells showed TCR γ gene rearrangement.[19] Therefore, TCR γ gene rearrangement is not always T cell specific, and the role of TCR γ gene rearrangement in pre-T-ALL cells will be examined until the function of TCR γ molecule[20] is elucidated.

Leukemia cells in case no. 4 expressed not only CD7 and CD5 antigens but also CD3 antigen, and both TCR β and γ gene rearrangement was observed. These data indicate that case no. 4 had more mature characteristics of thymocytes

than the other three pre–T-ALL cases, and the leukemia cells are thought to express TCR-CD3 complex on the cell surface.

It is well known that TPA induces the differentiation and expression of cell surface antigens in various hematopoietic cell lines and in fresh leukemia cells. TPA stimulation of thymocytes, peripheral T cells and some T cell lines has been reported to induce the expression of IL-2 receptor on their cell surface membranes.[21-24] It was of interest to know whether TPA could induce the IL-2 receptor (Tac antigen) on pre–T-ALL cells that are the counterpart of normal immature precursor thymocytes. In the present study, all of four pre–T-ALL cells began to express Tac antigen after 12 hours of incubation with TPA. However, leukemia cells of three cases without rearrangement of TCR β and TCR γ genes expressed no new T cell antigen by the incubation with TPA for up to 72 hours. These findings suggest that the intracytoplasmic pathway for Tac antigen induction has already existed in immature pre–T-ALL cells expressing no TCR-CD3 complex on their cell surface membranes. TPA stimulation of the leukemia cells of case no. 4, which showed CD3 positive with both TCR β and TCR γ gene rearrangements, induced not only IL-2 receptor but also CD4 and CD8 antigens. It is unlikely that the contaminated PB-T cells in leukemia samples have proliferated by TPA stimulation, and CD4 and CD8 antigens have appeared on these normal cells, because PB-T cells were depleted from leukemia samples, and CD2 cell surface phenotype did not appear at all. Therefore, it is suggested that only late stage of precursor thymocytes with the expression of TCR-CD3 complex will have the capacity to differentiate into more mature stages of thymocytes accompanying the expression of CD4 and CD8 with TPA stimulation. The binding assay of ^{125}I-IL-2 to those pre–T-ALL cells revealed that IL-2 does bind to the IL-2 receptor on those cells with low affinity. Although the effect of IL-2 on early thymocytes is controversial, our data shows that exogeneous IL-2 does not influence the proliferation of TPA-stimulated pre–T-ALL cells.

ACKNOWLEDGMENT

The authors are very grateful to T. Noumi for technical assistance, to Dr T. Fukuda of Aichi Red Cross Blood Center for his advice and encouragement throughout this study, and to staff members of the hematology and pediatric clinics of Nagoya University Hospital for providing leukemia cell samples.

Localization of Surface vWF on Resting and Stimulated Platelets

By Jacob H. Rand, Ronald E. Gordon, Ronald R. Uson, and Barry J. Potter

We used immunoelectron microscopic localization techniques to investigate whether platelets stimulated by ADP or ristocetin in the plasma milieu bind von Willebrand factor (vWF) to their surfaces. We found by both peroxidase- and ferritin-based methods that unstimulated platelets lack vWF on their surfaces, whereas platelets that are stimulated with ADP or ristocetin have vWF associated with their surfaces. The specificity of the findings was confirmed by absorption studies using severe von Willebrand disease (vWD) and hemophilic plasmas. The anti-vWF antibodies were blocked by incubation with hemophilic plasma but not by incubation with severe vWD plasma. Thus, in the plasma environment, in the presence of fibrinogen, vWF becomes associated with the platelet surface subsequent to stimulation with ADP or ristocetin.

©1987 by Grune & Stratton, Inc.

VON WILLEBRAND FACTOR (vWF) is a multimeric glycoprotein that supports the adhesion of platelets to vascular subendothelium under high shear rate conditions.[1] vWF can bind to two different platelet binding sites, glycoprotein Ib (GP-Ib) and the glycoprotein IIb/IIIa complex (GP IIb/IIIa). Binding to GP-Ib requires the presence of ristocetin,[2-5] and binding to GP-IIb/IIIa requires stimulation by agonists such as ADP and thrombin.[6,7] Since a physiologic counterpart for ristocetin has not been clearly identified, and since it has been demonstrated that, in the normal plasma milieu, fibrinogen would block the ability of the GP-IIb/IIIa complex to bind vWF present in the external milieu,[8-10] we decided to investigate whether vWF binds to platelets stimulated by ristocetin and by ADP using immunoelectron microscopic localization techniques. We examined binding of vWF morphologically, under conditions that would minimize the potentially perturbing influences of platelet washing steps and vWF purification and labeling.

MATERIALS AND METHODS

Antisera. Monospecific rabbit anti-human vWF was prepared as previously described.[11] Horseradish peroxidase-conjugated sheep Fab anti-rabbit IgG (HRP-SARG) and ferritin-conjugated SARG were obtained from Polysciences (Philadelphia). Controls for specificity of antigen localization included absorption of anti-vWF in plasma from a patient with severe classical hemophilia-factor VIII deficiency (George King, Overlook, KS), which contained normal levels of vWF and lacked coagulation factor VIII, and absorption in plasma from a patient with severe recessive von Willebrand disease (vWD) (George King, Overlook, KS), which was deficient in coagulation factor VIII and lacked detectable levels of vWF. Rabbit anti-human thyroglobulin was obtained from Dakopatts (Dako, Santa Barbara, CA).

Platelets. Normal blood was collected by clean venipuncture into a final concentration of 0.11 mol/L sodium citrate. Platelet-rich plasma (PRP) was separated after centrifugation at 250 g for ten minutes at room temperature. Platelet counts were maintained at ~300,000/μL by dilution with PRP. Aliquots of PRP with volumes of 0.9 mL were then incubated at 37°C for 15 minutes with constant rotation following the addition of 0.1 mL of the following materials: ristocetin (Lenau, Denmark), at a final concentration of 1.5 mg/mL, ADP (Sigma, New York) at a final concentration of 20 μmol/L, and iso-osmolar phosphate buffered saline (PBS) pH 7.2. Under these conditions both ristocetin and ADP-stimulated platelets formed fine aggregates. Following the incubation periods, the PRPs were fixed by addition of an equal volume of 4% paraformaldehyde in PBS for 30 minutes. The platelets were then centrifuged for five minutes in an Eppendorf microfuge (Brinkman Instruments, Westbury, NY) and prepared for immunoelectron microscopy.

Immuno-localization. Following fixation, the platelets were resuspended and washed for 12 hours in PBS-10% sucrose. The washed platelets were then resuspended in a 1:40 dilution of rabbit anti-vWF, as previously described, in which they were incubated for one hour at 37°C. Again, the platelets were centrifuged and washed three times in PBS-10% sucrose. The platelets were then resuspended in 1:40 dilution of SARG (1.25 μg/mL) coupled to either HRP or ferritin (Polysciences, Phila., PA) and then incubated for one hour at 37°C. After three ten-minute washes in PBS-10% sucrose, as described above, the platelets were treated with 3% gluteraldehyde in PBS-10% sucrose in order to fix the antibodies in place. The platelets were then resuspended and washed three times in PBS. In the case of the ristocetin and ADP stimulated platelets, fine aggregates were observed during the washing steps. The platelets that had been treated with HRP-SARG were then incubated for seven to ten minutes in a 0.5% solution of 3.3-diaminobenzidine tetrahydrochloride (DAB) at a final concentration of 0.01% H_2O_2. Both the HRP-SARG and ferritin treated tissues were then treated with 1% unbuffered osmium tetroxide, were dehydrated with ethanol followed by propylene oxide, and were then embedded in Epon 812.

Controls. Several controls were used to check for the specificity of antigen localization. In order to ensure that we were not localizing nonantigenically bound antibody, platelets were also treated with nonimmune rabbit serum before they were treated with HRP-SARG and DAB. As noted above, in order to check for antibody specificity, the rabbit anti-vWF was absorbed in plasma from a patient with classical hemophilia-factor VIII deficiency and in a severe vWD plasma. Additional controls included treatment of platelets with SARG followed by DAB without any preceeding rabbit antiserum, and treatment of platelets with DAB alone. In order to check whether localization might be due to nonspecific trapping of protein from plasma during the course of processing, platelets activated by ADP and ristocetin were also incubated with rabbit anti-human thyroglobulin followed by staining with both the ferritin and the peroxidase methods.

One-μm thick sections were cut from all blocks and examined by light microscopy. The presence and distribution of dense precipitates were evaluated under double-blind conditions. Areas from each block were sectioned for transmission electron microscopy. The

Table 1. Immunoelectron Microscope Localization of vWF on Platelet Membranes

	Unstimulated Platelets	ADP	Ristocetin
Rabbit anti-vWF	−	+	+
Rabbit anti-vWF absorbed in hemophilic plasma	−	−	−
Rabbit anti-vWF absorbed in vWD plasma	−	+	+
Nonimmune rabbit serum	−	−	−

sections were examined without additional staining with heavy metal salts.

RESULTS

Platelets treated with anti-vWF probed by ferritin-conjugated antibodies were more revealing than those probed with peroxidase conjugated antibodies. In each instance, platelets treated with ristocetin and ADP demonstrated significant binding of vWF between adjacent platelets (Table 1, Figs 1 and 2). Interestingly, there was a paucity of labeling at sites away from platelet adjoinment.

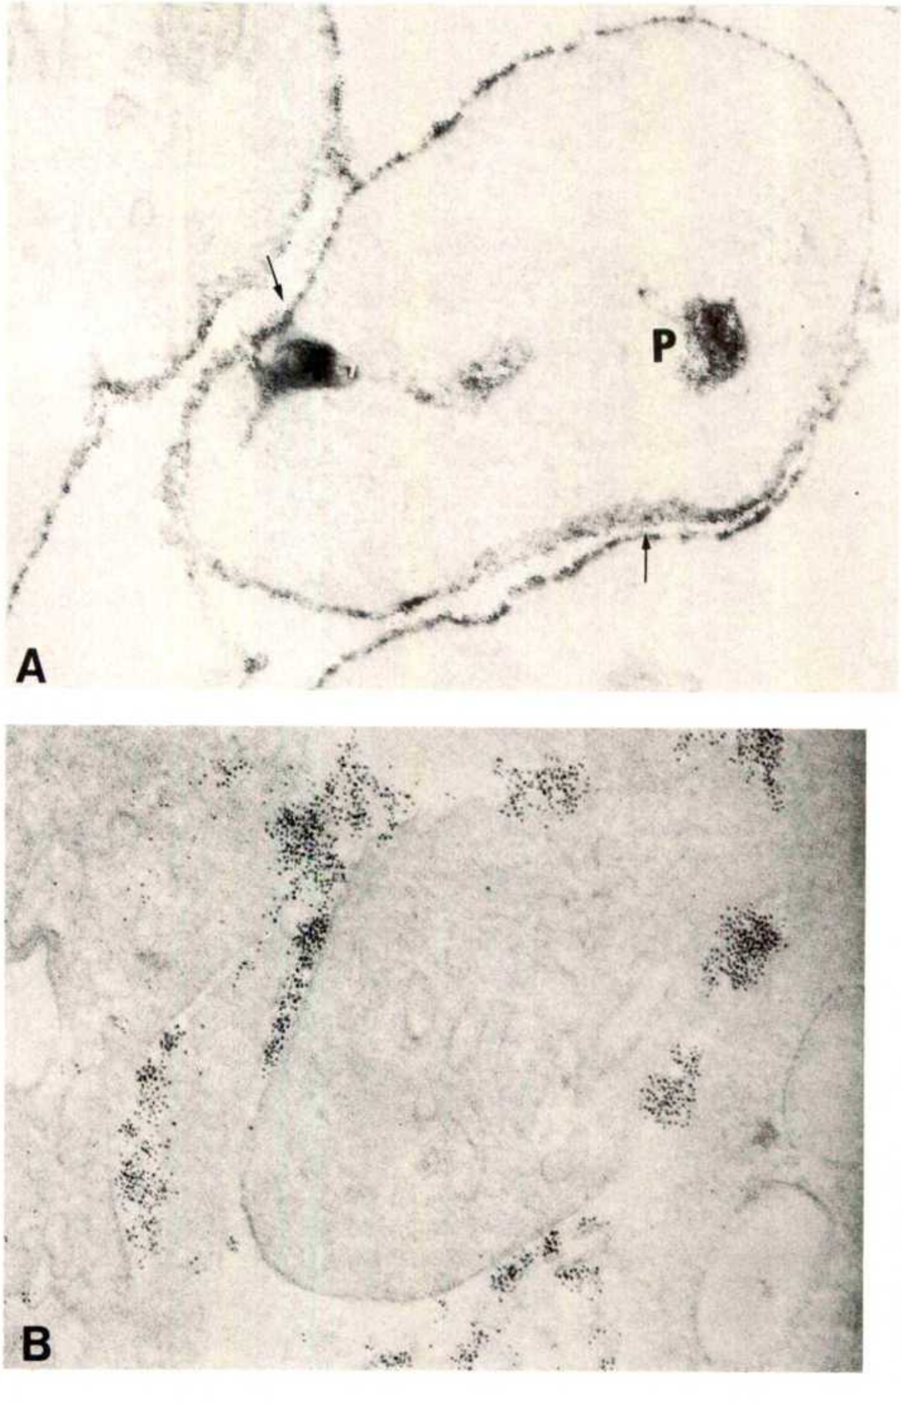

Fig 1. Electron micrographs of platelets treated with ristocetin, fixed in paraformaldehyde and sequentially treated with rabbit anti-human vWF, sheep anti-rabbit IgG coupled with (A) horseradish peroxidase and (B) ferritin, and then fixed with gluteraldehyde. The peroxidase-treated tissue was then incubated with 3,3-diaminobenzidine with H_2O_2 before embedment in Epon 812. Thin sections observed without prior staining with heavy metal salts exhibited significant vWF binding (arrows) to plasma membranes of adjoining platelets. Peroxidase labeled granules (P) are present within platelets. (A, Magnification ×56,000; B, magnification ×72,600.)

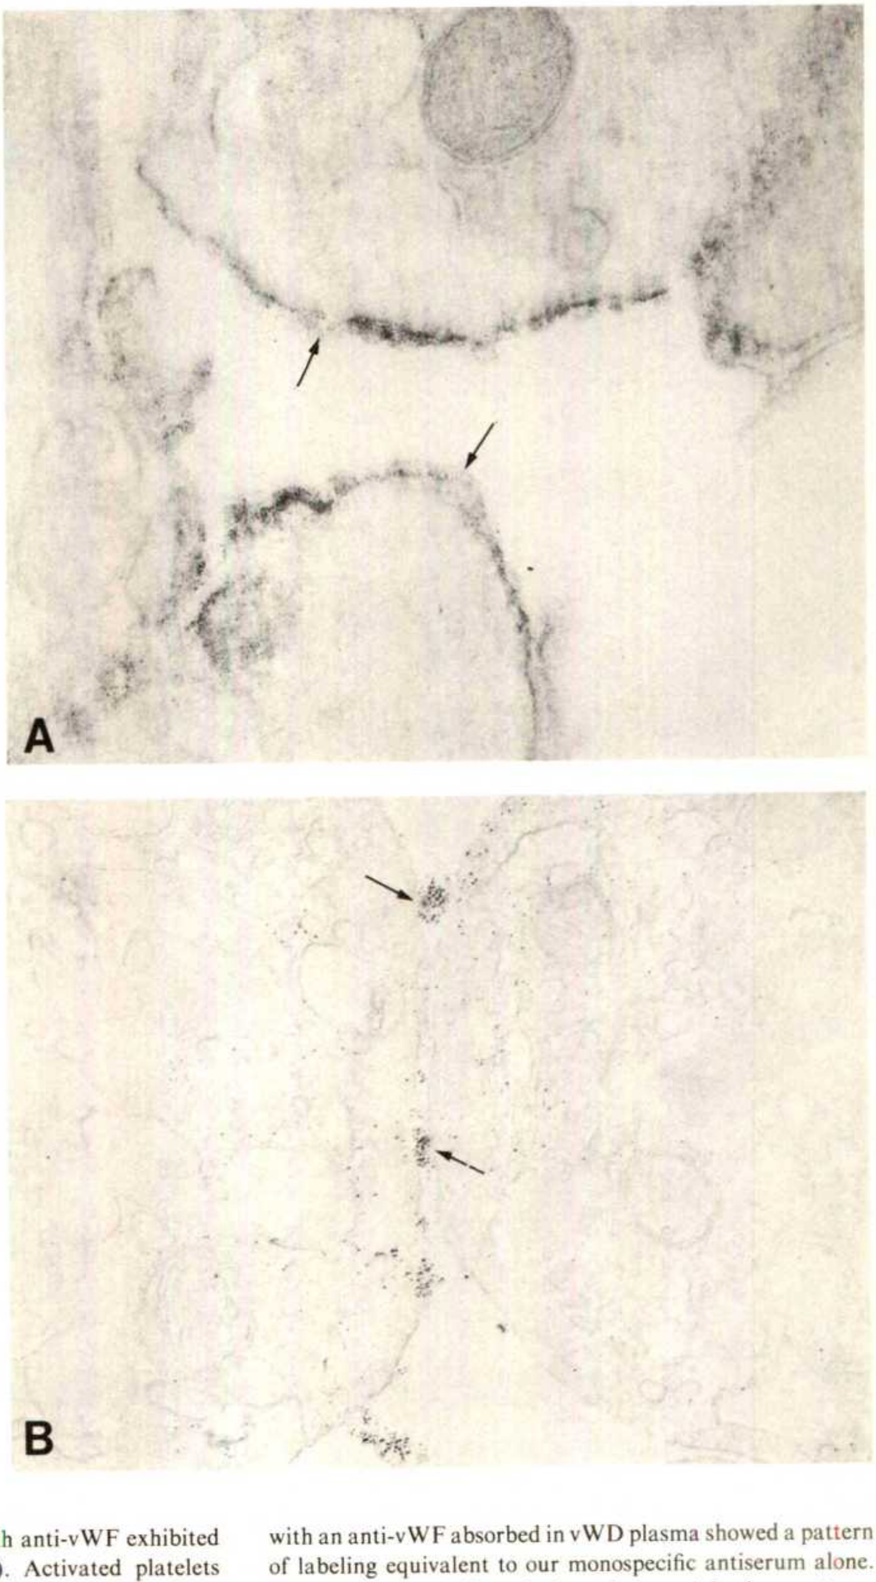

Fig 2. Electron micrographs of platelets treated with ADP and processed as described in Fig 1. The platelets exhibit sites of vWF binding (arrows) on the surfaces of adjacent platelets treated with antibody coupled to (A) horseradish peroxidase and (B) ferritin. (Magnification ×52,800.)

PBS-treated platelets incubated with anti-vWF exhibited little or no surface labeling (Fig 3). Activated platelets incubated with anti-vWF absorbed in hemophilic plasma followed by the second conjugated antibodies showed no surface labeling (Fig 4). Activated platelets treated with anti-thyroglobulin antibodies also showed no surface labeling. Platelets treated with SARG followed by DAB and by DAB alone, showed no surface labeling. Platelets incubated with an anti-vWF absorbed in vWD plasma showed a pattern of labeling equivalent to our monospecific antiserum alone. These controls indicated that the precipitation patterns observed represent specificity bound vWF and not trapped vWF, another antigen, or nonspecific immunoglobulins.

Since the platelets were not stained with heavy metal salts, ultrastructural elements such as platelet granules were not well defined. Sections treated by the peroxidase method with

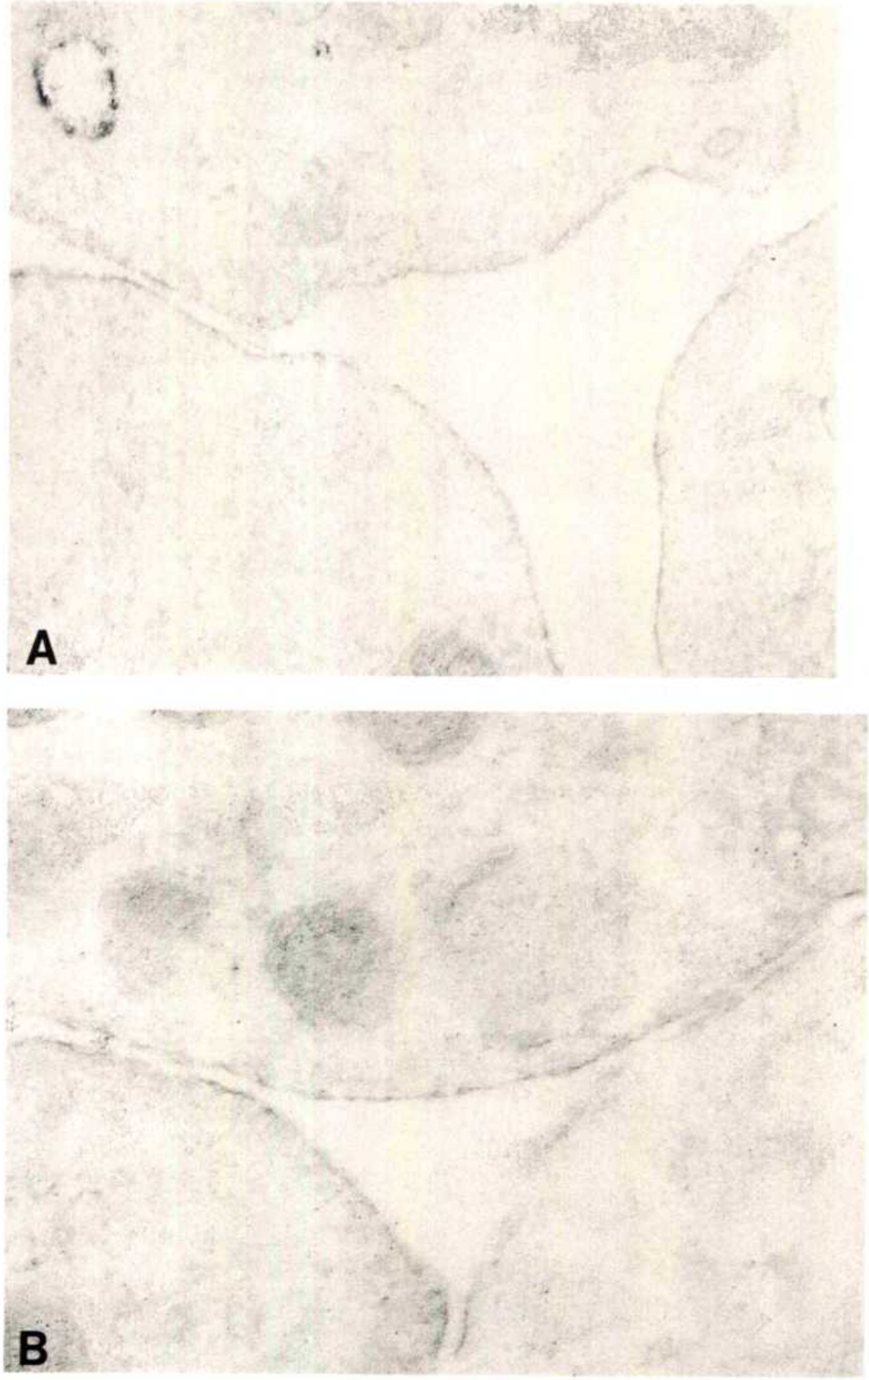

Fig 3. When PRP is incubated with PBS in place of ristocetin or ADP, fixed with paraformaldehyde and then processed as described in Fig 1, there are few or no sites of vWF localization detectable on the platelet surfaces as seen with (A) horseradish peroxidase and (B) ferritin coupled antibodies. (A, Magnification ×82,500; B, magnification ×59,400.)

DAB showed peroxidase labeling granules (Figs 1A and 3A). Because of endogenous peroxidase activity, antibody-linked peroxidase could not be distinguished from endogenous activity in the granules.

DISCUSSION

There have been several studies of vWF binding to platelets. These demonstrated ristocetin-dependent binding of vWF to binding sites on platelets by using I^{125}-vWF derived from lyophilized factor VIII concentrate or cryoprecipitate and washed platelets that had been collected in EDTA.[3-5] With respect to binding in the absence of ristocetin, Fujimoto et al demonstrated that thrombin as well as ADP and Ionophore A23187 induces a receptor for I^{125}-vWF in washed platelets collected from citrated blood.[6] Ruggeri et al showed that the ristocetin induced binding of vWF by platelets is mediated by GP-Ib, whereas the thrombin induced binding of vWF is mediated by GP-IIb/IIIa.[7] However, Pietu et al demonstrated that GP-IIb/IIIa does not bind vWF in the presence of normal fibrinogen levels.[8] Schullek et al, in a system using an I^{125}-tagged monoclonal anti-vWF as a probe, showed that thrombin and ADP/epinephrine induced bind-

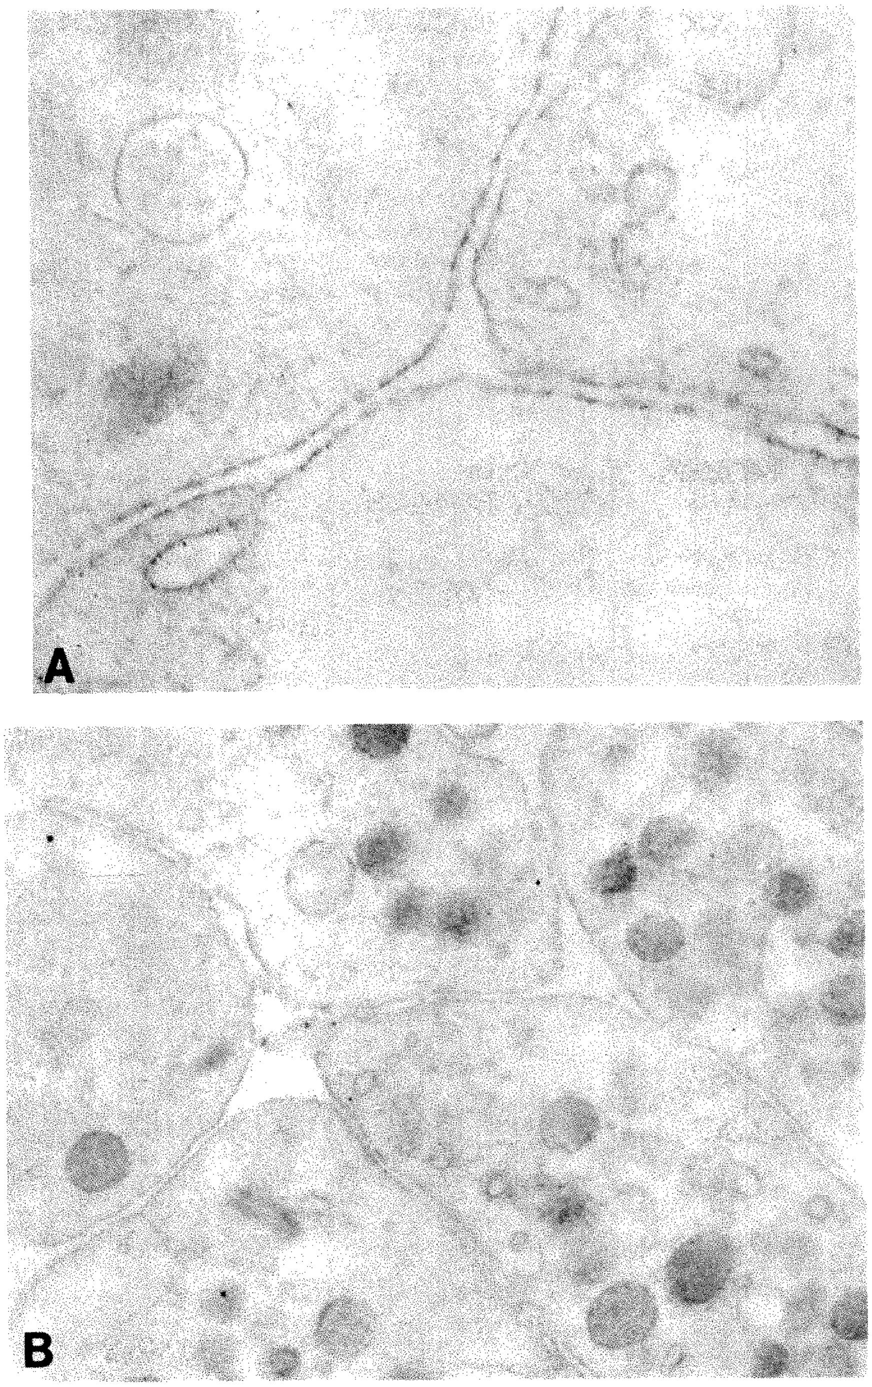

Fig 4. Micrographs of technique and immunologic controls all exhibit the absence of either (A) peroxidase reaction product or (B) ferritin as evidenced here by the lack of staining on platelets treated with ristocetin, fixed, and then incubated with antibodies to vWF which had been previously absorbed in hemophilic plasma. (A, Magnification ×66,000; B, magnification ×28,000.)

ing of vWF to washed platelets does not occur in the presence of plasma.[10]

The evaluation of vWF binding to platelets is frought with difficulties. The purified vWF may contain degraded subunit forms even under relatively optimal conditions.[11] The ligand is heterogeneous, consisting of a range of multimer sizes.[12,13] There is ambiguity about the nature of the platelet binding site with GP-Ib binding vWF only in the presence of ristocetin, and GP-IIb/IIIa, although capable of binding vWF in purified systems, appearing to function primarily as a fibrinogen binding site in plasma. The isolation and washing of platelets may perturb surface binding sites. Finally, vWF present within the platelet's α-granule[14] may interfere with tracers by binding to surface sites during either isolation and washing of platelets, or during platelet stimulation. In considering the complexity of the problem, we chose to use immunolocalization techniques that would perturb the system as minimally as possible.

In this study, we found that both ristocetin and ADP promote clusters of precipitate representing vWF that are most prominent at platelet contact points with other platelets. Thus, in addition to vWF's role in promoting platelet adhesion to vascular subendothelium, we observe morphologic evidence for the presence of vWF at platelet contact sites. Our studies do not relate the surface vWF to the putative receptors, GP-Ib or GP-IIb/IIIa.

The specificity of the observed localization patterns is supported by the equivalent findings with antiserum that was absorbed in vWD plasma. The lack of observable precipitates with anti-vWF that had been absorbed in factor VIII deficient plasma indicates that the precipitates did not reflect localization of fibrinogen, coagulation factor VIII, Fc receptor binding of immunoglobulins or, in the case of HRP-SARG, endogenous peroxidase activity. The latter two possibilities have also been excluded by the negative results of our additional controls which included: (1) nonimmune rabbit serum, (2) the substitution of a rabbit antibody against human thyroglobulin, (3) the omission of a primary rabbit anti-serum, and (4) treatment beginning with the peroxidase substrate, DAB.

The localization of vWF between activated platelets may relate to its role in supporting the formation of platelet thrombi. vWF is an adhesive glycoprotein that supports platelet adhesion to exposed vascular subendothelium[1] and also appears to support platelet thrombus formation.[15] In the case of platelet adhesion, vWF is present on the subendothelial surface where it promotes adhesion.[16-18] However, in order for vWF to play a similar role in platelet thrombus formation, vWF from plasma, or released from endogenous stores must attach to platelet surface binding sites. Evidence for such binding is presented in this study.

The source(s) of the vWF that associates with the platelet surface following stimulation by ADP in the plasma environment is not yet known. As noted above, it is clear that washed platelets stimulated by ADP can bind exogenous vWF when fibrinogen is absent. In the case of unwashed platelets stimulated in plasma, the surface bound vWF might be released or externalized α-granules, might yet be bound from plasma, or might come from both sources.

In conclusion, our immunolocalization studies have demonstrated that following activation, vWF shows distinct localization patterns on the platelet surface. This association occurs even in the plasma milieu, in the presence of normal fibrinogen levels. This surface vWF may explain the observation that vWF promotes the presence of platelet aggregates on vascular subendothelium.[15]

Specific Adsorption of HTLV-I to Various Target Human and Animal Cells

By Karen Krichbaum-Stenger, Bernard J. Poiesz, Paul Keller, Garth Ehrlich, Jerrie Gavalchin,
Bruce H. Davis, and Janet L. Moore

In this report, we describe a flow cytometric analysis of HTLV-I specific binding to fresh and cultured cells on a single cell basis. This assay uses rhodamine hydrocarbon tagged, purified HTLV-I virions according to the procedure originally described for avian retroviruses. Successful HTLV-I transmission was detected by analysis of integrated HTLV-I DNA, virion-associated reverse transcriptase, and/or intracellular HTLV-I core antigen p19 expression. Only a specific virus–cell interaction was detected because nonrhodamine-tagged homologous virus or related HTLV-II interfered with tagged HTLV-I binding. In contrast, an unrelated, nonlabeled animal retrovirus was unable to block tagged HTLV binding. Of the cell lines tested, 2 nonlymphoid mammalian and 3 human lymphoid bound significantly high to moderate levels of HTLV-I–tagged virions. The other three human lymphocyte cell lines were insensitive to HTLV-I adsorption. A direct correlation was observed between HTLV-I binding sites and infectivity of human lymphoid cells alone and not other nonlymphoid animal cells. Fresh normal human mononuclear cells bound low levels of HTLV-I virions. As expected, T lymphocytes demonstrated more binding than did the non-T cell population. Enhancement of HTLV-I cell binding in a subpopulation of mononuclear target cells was achieved with phytohemagglutinin (PHA) activation and interleukin 2 (IL2) stimulation, which correlates well with previously published infectivity studies.

THE HUMAN T CELL lymphoma/leukemia virus I and II are associated with adult T cell leukemia (ATL)[1-5] and T cell hairy cell leukemia, respectively.[6] Functionally, both viruses transform T lympocytes in vitro. In vitro infection of a wide range of human and animal cells by both viruses has been reported. Using cocultivation techniques, normal, T$_4$, T$_8$, and non-B/non-T lymphocytes can be infected.[7-10] Lymphocytes from several other species can also be infected.[11] Human-derived cell lines, including B lymphocytes, osteogenic sarcoma cells, fibrosarcoma cells, diploid fibroblasts, and endothelial cells can also be infected.[12-16]

The only nonhuman, nonlymphoid cell line capable of HTLV-I transmission is feline kidney fibroblasts.[15] The in vitro host range of HTLV-II differs slightly from HTLV-I. Although equally transmissible to human T lymphocytes, HTLV-II more efficiently infects B lymphocytes and is not transmitted to human fibrosarcoma, human osteosarcoma, or feline kidney fibroblasts.[15]

Despite their varied in vitro tropism, however, HTLV-I and HTLV-II have been associated only with human malignancies exhibiting the T$_4$ T lymphocyte cell surface phenotype.[3,6] This in vivo cellular tropism of HTLV-I may be regulated at several points in the virus life cycle: (a) viral adsorption and penetration, governed by specific viral target membrane receptors; (b) viral genomic integration into target cell DNA; and (c) RNA transcription of proviral DNA, requiring noncoding, viral-specific, regulatory sequences called long terminal repeats (LTRs).

Several lines of evidence support the concept that the cell surface receptors may be a key in the determination of HTLV-I and HTLV-II cell tropism in vivo. First, although the major envelope glycoproteins of HTLV-I and HTLV-II are distinct, they are more homologous than the LTR transcriptional regulatory sequences of HTLV-I and HTLV-II.[17,18] In addition, by vesicular stomatitis virus (VSV) pseudotype interference studies, these two related human retroviruses appeared to share the same cell membrane receptors.[15] Another argument involves the lack of site-specific integration of HTLV-I into cellular chromosomal DNA.[19,20] Examination of HTLV-I proviral DNA integration sites in fresh and cultured cells has indicated that the virus does not integrate in any preferential site or chromosome.[19,20] Thus, this virus does not appear to directly regulate RNA transcription of an adjacent cellular gene by *cis* activation. Last, recent data suggest that the molecular mechanisms of HTLV-I transformation involves *trans* activation of HTLV-I expression itself and possibly a yet unknown, oncogenic gene at a distant chromosomal location by the HTLV-I pX protein, LOR.[21] These observations suggest that HTLV-induced cell transformation is primarily dependent on the susceptibility to virus attack at the specific cell membrane receptor level. Accordingly, the present studies focus on the development of an assay for relative quantitation of HTLV-I and HTLV-II cell membrane binding sites by flow cytometric analysis of rhodamine hydrocarbon-labeled HTLV bound to fresh and cultured cells on a cell–cell basis, as previously described for avian retroviruses.[22-24]

MATERIALS AND METHODS

Cells. The following cell lines were maintained in culture: HUT 102-B2, an HTLV-I–producing, mature neoplastic T lymphocyte from a lymph node of an ATL patient[3]; MT-2, umbilical cord blood mature T lymphocyte exogenously infected with HTLV-I[25]; Mo-T, HTLV-II–producing, human T lymphocyte from F. Ruscetti, National Institutes of Health (NIH); and the virus negative lines;

Molt-4, an immature T lymphocyte derived from a patient with acute lymphocytic leukemia; HUT 78, mature T lymphocytes derived from a patient with cutaneous T cell lymphoma[26]; FR-45, continuous human B lymphocytes from a normal donor from F. Ruscetti, NIH; NK-41, continuous human natural killer cells from a normal donor established by F. Ruscetti, NIH; VERO, an African green monkey kidney cells; and SC-1, a wild mouse fibroblasts from C. Kozak, NIH. Normal adult peripheral blood mononuclear cells were obtained by centrifugation of heparinized blood on a Ficoll-Hypaque density gradient. Activated T cells were generated by culturing the above cells in RPMI 1640 media, 10% fetal calf serum (FCS), 5 μg/mL phytohemagglutinin (PHA), and 10% delectinated, partially purified human interleukin 2 (IL 2) (Cellular Products, Buffalo).

T cell and non-T cell–enriched population were prepared by forming E rosettes with treated sheep RBCs (SRBCs) and performing sedimentation on lymphocyte separation media (Litton Bionetics, Kensington, MD).[27]

Purification of retrovirus particles. Virions of HTLV-I, HTLV-II, or a B tropic, ecotropic murine leukemia virus (2557) from a BALB/c mouse were purified from media conditioned by the following cell lines; HUT 102-B2, Mo-T, and SC-1, respectively. To prevent possible disruption of intact whole virions or removal of their envelope proteins, a gentler purification was performed in comparison to previously described more stringent virus purification techniques.[3] After removal of cultured cells from 2 to 20 L growth media (RPMI 1640, 10% FCS, 1% penicillin-streptomycin by sedimentation at 870 g for 15 minutes, virions were concentrated by centrifugation of the supernatant at 30,500 g for 45 minutes and resuspended in 10 mmol/L Tris-HCl, pH 7.4, 0.1 mol/L NACl, 1 mmol/L EDTA (TNE buffer). Pooled virions were then spun through 30% sucrose in TNE buffer onto a 45% sucrose cushion by ultracentrifugation on two consecutive discontinuous 30% to 45% sucrose density gradients at 89,400 g for 2.5 hours. Virions were stored in 200-μL aliquots at −70°C.

Reverse transcriptase assay. Virus particles were quantitated according to the amount of reverse transcriptase activity present per lot of purified virions. Assessment of reverse transcriptase activity was carried out as previously described.[4] Results were expressed in values of pmoles of ^{3}H-deoxyguanidine monophosphate incorporated per hour.

Labeling of virus with a fluorescent membrane probe. Rhodamine-16 (R-16) is a fluorescent dye (rhodamine) covalently linked to a saturated hydrocarhon 16 carbons long.[22] The synthesis of similar membrane probes is described in ref. 23. The hydrocarbon chain causes the fluorescent dye to partition into lipid-rich viral envelopes and to remain there preferentially.[23] The labeling technique that maintains infectivity of the virus and target cell viability was established previously.[22] In brief, virions were conjugated with rhodamine-16 (HTLV/R-16) by incubating gradient purified virus in a final concentration of 0.25 mmol/L R-16 in 5% dimethyl sulfoxide. Unbound R-16 and any free R-16 were removed by two consecutive discontinuous sucrose velocity gradient centrifugations. The virus was concentrated on a glycerol cushion, and the buffer above the cushion was analyzed for the presence of any remaining free R-16.

Sample preparation for flow cytometric analysis. The adsorption procedure of R-16–labeled virions to various cells was performed as follows: Various concentrations (1 HTLV-I/R16 concentration refers to the equivalent number of virions containing 50 pmoles of reverse transcriptase activity) of R-16–labeled virions in glycerol and TNE buffer were incubated with 7.5 × 10^5 target cells in suspension in 0.2 mL minimal essential medium (MEM), 1% FCS and 2 μg/mL polybrene at 4°C, or room temperature. At 4°C, adsorption of HTLV-I occurs without subsequent penetration, whereas both viral adsorption and penetration of the target cell are possible at 25°C.[28] After the virus–cell interaction, cells were spun at 400 g for 5 minutes at 4°C, supernatant was removed, and cells were resuspended in 0.4 mL fresh medium (MEM, 1% FCS, and polybrene). Samples were filtered through 44-μm nylon mesh to remove clumps and were kept on ice during flow cytometric analysis to maintain cell viability and to prevent significant viral penetration.[22]

Multiparameter flow cytometric analysis. Flow cytometric (FCM) measurements were performed on the Coulter EPICS V (Coulter Electronics, Hialeah, FL) equipped with a 4-W argon laser. Fcm measurements (relative fluorescent intensities) of rhodamine-labeled HTLV-I adsorbed cells resulted from excitation by the 514-nm line of the cytometer's argon-ion laser, and the fluorescence emitted was monitored by detectors at wavelengths >610 nm using 530-nm short-pass interference and 570-nm long-pass absorbance filters.[22] Data were expressed in histogram form. Each histogram is based on 10,000 events fitting the forward angle and 90° light-scatter gates to reduce the contribution of dead or clumped cells; the rhodamine fluorescence was quantitated. Each sample was screened for background fluorescence representing autofluorescence of cells in the absence of rhodamine. The distribution of fluorescence-positive cells was expressed on the *y* axis and the increasing intensity of fluorescence was expressed on the *x* axis on a log scale. The mean channel fluorescence data for all samples were converted to relative linear fluorescence values using a log to linear conversion method[29] to allow better assessment of experiments.

Competitive inhibition studies using HTLV. Binding studies for the competition analysis were carried out as described above, except that prior to the addition of rhodamine-tagged virions, cells were incubated for 1½ to 2 hours with varying amounts of unlabeled HTLV-I, HTLV-II, and/or murine leukemia virus (MLV) (as determined by relative reverse transcriptase activities).

HTLV transmission assay. Cocultivation of HTLV-I–positive donor, neoplastic T cells with various human lymphoid target cells was carried out as described.[8] Resultant cell lines were assessed for HTLV-I production by assaying for extracellular reverse transcriptase and intracellular HTLV-I p19 core protein. The presence of integrated HTLV-I proviral DNA in the transformed cells was determined by dot blot or Southern blot hybridization using an HTLV-I cloned DNA probe.[8]

HTLV p19 detection. Indirect immunofluorescent assays for HTLV-I p19 using an anti–HTLV-I p19 monoclonal antibody were performed by a previously described technique.[8]

Nucleic acid hybridization. High-mol-wt DNA was extracted from the target, donor, and cocultivated cells and transferred onto nitrocellulose filters as previously described.[8] Dot blot or Southern blot hybridization analysis was performed with these nitrocellulose filters and a radiolabeled HTLV-I *gag-pol* DNA sequence, pATK 32 (a gift of Dr M. Yoshida).

RESULTS

Binding site saturation. Figure 1 shows an HTLV-I/R-16 MT-2 cell binding saturation curve, established with increasing concentrations of gently purified HTLV-I labeled with R-16 and a constant number of target cells and time of adsorption. The observed relative mean fluorescence increased in a linear manner at the lower concentrations of HTLV-I/R-16. The plateau of virus adsorption was reached at an HTLV-I/R-16 inoculum containing 25 pmoles of reverse transcriptase, indicating significant saturation of binding sites. For this reason, the concentration of HTLV-I/R-16 chosen to bind 7.5 × 10^5 target cells in a standard

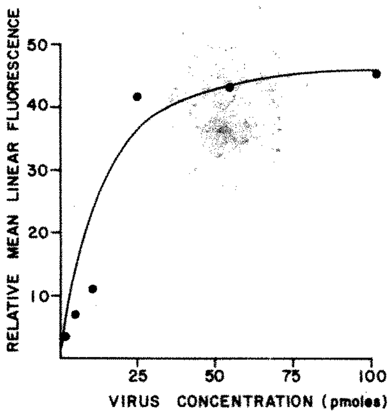

Fig 1. A saturation curve of HTLV-I binding to MT-2 cells using R-16–labeled HTLV-I and flow cytometry; 7.5 × 10^5 MT-2 cells were adsorbed for 30 minutes with increasing concentrations of HTLV-I/R-16 and analyzed in an EPICS V flow cytometer as described in the Materials and Methods section. The *x* axis scale represents the number of pmoles of reverse transcriptase activity in each virus adsorption sample.

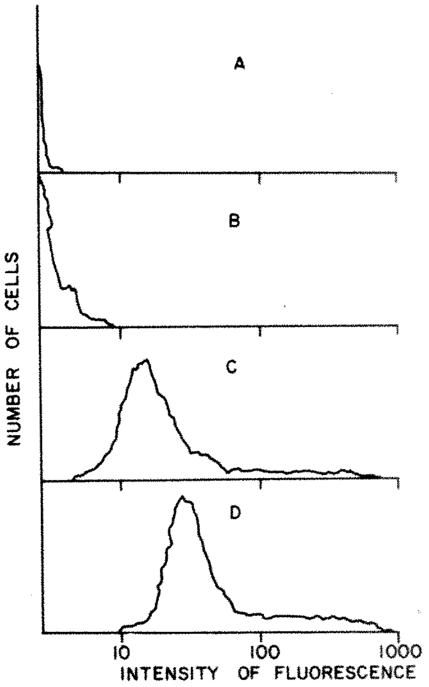

Fig 2. The distribution of HTLV-I binding sites on HTLV-I–susceptible HUT 102-B2 cells. The frequency of cells in each fluorescence category is plotted on the *y* axis against the cytometer detected intensity of fluorescence on the *x* axis (scale 0 to 1,000). (A) Control, unadsorbed HUT 102-B2 cells.[1] (B) HUT 102-B2 cells incubated with virion-free supernatants from an equivalent amount of HTLV-I/R-16 virus preparation as in D after removal of the labeled virions by centrifugation.[2] (C) Adsorption of an equivalent amount of HTLV-I/R-16 as in D to HUT 102-B2 binding sites after competition with unlabeled HTLV-I.[15] (D) HTLV-I/R-16 bound to HUT 102-B2 culture cells.[30] In Figs 2–6, numbers in parentheses indicate relative mean fluorescence.

assay was 50 pmoles of reverse transcriptase containing HTLV-I/R-16.

HTLV-I cell membrane binding assay. In all experiments, viable and nonviable cells were simultaneously analyzed by using forward-angle and 90° light-scatter parameters, but only the R-2 signals from 10,000 viable cells were measured. Figure 2 illustrates characterisic binding curves of free R-16 and R-16–labeled HTLV-I binding, respectively, to the prototype HTLV-I–producing cell line HUT 102-B2. For each cell population examined, the mean fluorescence bound per cell was recorded and the autofluorescence (fluorescence of cells in the absence of rhodinated virus) was checked. The HUT 102-B2–bound HTLV-I/R-16 histogram (Fig 2D) demonstrates significant adsorption of R-16–labeled virions to HUT 102-B2 cells with the maximum number of cells being represented by a mean fluorescence of 30, whereas the background autofluorescence of the same cells were minuscule (Fig 2A). The amount of fluorescence diminishes twofold (mean fluorescence 15) when target cells are incubated with unlabeled HTLV-I prior to the addition of rhodamine-tagged virions (Fig 2C). To rule out binding of residual free R-16 to HUT 102-B2 cells, HTLV-I/R-16 virus preparations were centrifuged to remove the labeled virions, and the supernatant (free of virions) was then reacted with HUT 102-B2 cells (Fig 2B). Results indicate that the HTLV-I/R-16 preparations are minimally contaminated with unbound R-16 or free rhodamine (Fig 2B).

MT-2 target cells infected with HTLV-I were chosen for reproducibility studies. Multiple tests on the same sample of HTLV-I/R-16 adsorbed MT-2 cells (instrument variability) and between replicate samples of HTLV-I/R16–bound MT-2 cells (assay variability) at near saturation showed a high degree of reproducibility. The SEM was 1.35% for instrument variability and 2.65% for assay variability (data not shown).

Homologous HTLV competitive binding. Figure 3 shows the histograms of relative HTLV-I/R-16 adsorption to several target cells and the effects of homologous virus competition. HTLV-I/R-16 adsorption specificity was clearly indicated in 57% and 52% of viable HUT 102-B2 and VERO cells, respectively (shaded areas). In contrast, only 28% of the normal adult peripheral blood mononuclear cells (PBMs) with PHA activation and IL 2 scored positive for HTLV-I/R-16 binding sites. These percentages are minimal numbers representing the number of HTLV-I/R-16–bound cells with a fluorescent intensity greater than the fluorescent intensity of tagged virion-bound cells that competed with homologous virus. The VERO cells expressed the highest number of specific fluorescent binding sites, more than twofold and fourfold higher than HUT 102-B2 and normal nonactivated adult PBMs, respectively (Fig 3B). Likewise, HUT 102-B2 cells showed an almost twofold greater rhodamine fluorescence over the PBMs tested (Fig 3A). The level of fluorescent intensity correlates with the surface area of these cells (data not shown). Homologous HTLV-I binding competition, with equal inoculums of unlabeled and labeled HTLV-I, reduced membrane bound fluorescence twofold in both the VERO and HUT 102-B2 cells. A concentration of unlabeled HTLV-I tenfold greater than HTLV-I/R-16 almost completely inhibited binding to HUT 102-B2 cells (data not shown). The activated adult PBM

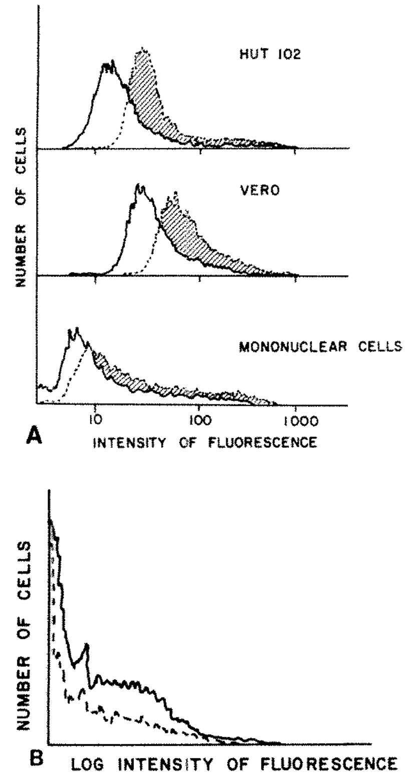

Fig 3. (A) HTLV-I adsorption to various target cells. The African green monkey kidney cell line, VERO, demonstrates the highest degree of rhodamine fluorescence, followed by HUT 102-B2 cells, and finally normal adult activated PBMs. The solid-line histogram represents cellular fluorescence resulting from the homologous competition between HTLV-I/R-16 and unlabeled HTLV-I virions in HUT 102 (21) VERO (41), and mononuclear cells (13), whereas the broken-line histogram represents the distribution of cellular binding sites of HTLV-I/R-16 alone without competition in HUT 102 (41), VERO (81), and mononuclear cells (20). Numbers in parentheses represent relative mean fluorescence. (B) HTLV-I adsorption to T-enriched (solid line) and non-T–enriched (broken line) PHA-activated normal PBMs.

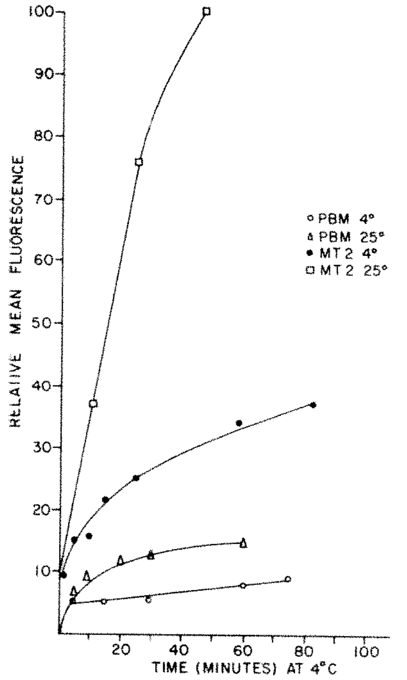

Fig 4. Effect of temperature on the binding rate of rhodamine-labeled HTLV-I virions to MT-2 culture cells and nonactivated adult PBMs. A constant amount of rhodamine-tagged HTLV-I virions were added to 7.5 × 10^5 target cells and incubated at either 4°C or 25°C for the time indicated on the *x* axis: MT-2 cells adsorbed with HTLV-I/R-16 at 25°C (–); MT-2 cells adsorbed with HTLV-I/R-16 at 4°C (O–O); PBMs adsorbed with HTLV-I/R-16 at 25°C (–); PBMs adsorbed with HTLV-I/R-16 at 4°C (O–O).

cells were more resistant to competition with unlabeled homologous HTLV-I (Fig 3C).

Kinetics of HTLV-I specific binding at 4°C and 25°C. To establish the rate of specific binding of HTLV-I/R-16 to susceptible MT-2 cells and fairly resistant adult fresh PBMs, the parameters of temperature and time were varied (Fig 4). At 4°C, the assay measures viral adsorption alone, whereas at 25°C the virus can bind and penetrate the cells, possibly allowing for multiple sequential binding of a single cellular binding site.[28] Fluorescent signals were recorded at minute intervals from the initial interaction of HTLV-I/R-16 and target cells. The rate of binding of HTLV-I/R-16 to MT-2 cells at 25°C proved very rapid and linear. No plateau was observed for 120 minutes. At 4°C, the rate of binding of HTLV/I/R-16 to MT-2 cells was much slower; within 15 minutes, 50% of the maximum cell-bound fluorescence was attained (Fig 4). The rate of binding subsequently plateaued at 60 minutes, followed by only minimal additional binding. These results are in accord with well established kinetics of specific virus–cell membrane receptor interactions at 4°C.[28] In comparison, the maximum binding of HTLV-I/R-16 to fresh, nonactivated adult PBMs at 4°C and 25°C was much less. The adsorption plateau was reached at both temperatures more quickly than in MT-2 (Fig 4). As expected, the maximum bound PBM fluorescent was significantly higher at 25°C than at 4°C.

Assay sensitivity. The low limit of detectability of HTLV-I cell binding sites was determined by mixing a small proportion of known high HTLV-I binding site cells (MT-2) with a large proportion of cells with low HTLV-I cell binding activity (nonactivated PBMs). A mixture of 90% of PBMs and 10% MT-2 cells (Fig 5B) and another of 95% PBMs and 5% MT-2 cells (Fig 5C) showed 26% and 19% viable fluorescent cells above an intensity of 34 (the left edge of the MT-2 curve) whereas only 13% of the viable pure population of PBMs bound fluorescence above an intensity of 34 (Fig 5A). After subtraction of fluorescent-bound PBMs, the number of HTLV-I/R-16–bound MT-2 cells in these mixed populations were calculated as 13% and 16%, respectively. These results indicate that a subset of the PBMs was probably HTLV-I binding site positive and that as little as 5% and 10% HTLV-I cell membrane binding site-positive cells was accurately detected in these heterologous population of cells.

Binding competition with an unrelated retrovirus. To demonstrate further the specificity of this virus membrane binding assay, an ecotropic MLV, which has no significant

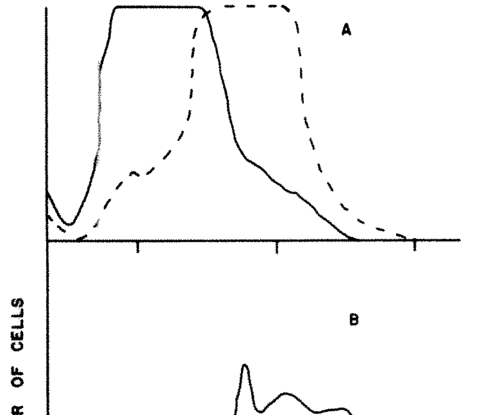

Fig 5. Sensitivity of the virus–cell binding assay. Histograms represent the frequency distribution of: (A) HTLV-I/R-16 bound to 100% PBM cells (O——O), HTLV-I/R-16 bound to 100% MT-2 cells (O---O). (B) HTLV-I/R-16 bound to a mixture of 90% PBMs and 10% MT-2 cells minus the histogram of HLTV-I/R-16 bound to 100% PBMs in A. (C) HTLV-I/R-16 bound to a mixture of 95% PBMs and 5% MT-2 cells minus the histogram of HTLV-I/R-16 bound to 100% PBMs in A.

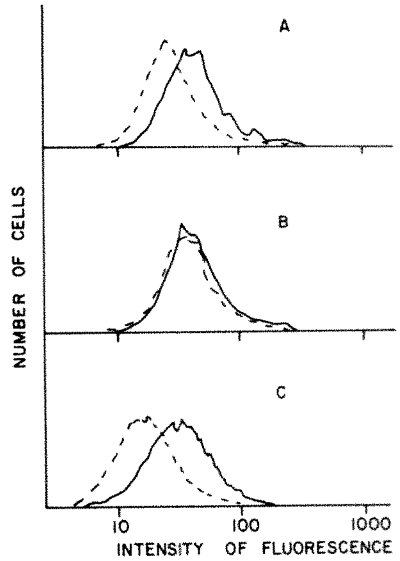

Fig 6. HTLV-I/R-16 binding competition with an unrelated retrovirus, MLV. Solid-line histograms represent frequency distribution of HTLV-I/R-16–bound MT-2 cells (43) in A and B, or MLV/R-16 bound SC-1 cells (31) in C without competition. Dashed-line histograms show distribution of fluorescent MT-2 cells reacted with homologous virus (HTLV-I) (29) in panel A or heterologous virus (MLV) (42) in B followed by adsorption of HTLV-I/R-16. In C, the dashed line represents frequency distribution of fluorescent-positive SC-1 cells exposed to homologous MLV prior to MLV/R-16 adsorption (16). Numbers in parentheses represent relative mean fluorescence.

primary nucleotide sequence homology to HTLV-I and a restricted mouse or rat cell host range was used in cross-interference studies.[30,31] Figure 6A shows histograms of MT-2 cells that revealed a twofold decrease in fluorescent intensity with HTLV-I homologous interference whereas only slight interference was visualized with MLV adsorption prior to HTLV-I challenge (Fig 6B). In contrast, MLV membrane binding to susceptible SC-1 cells and significant binding inhibition (fourfold) with homologous virus was clearly observed (Fig 6C).

Correlation between HTLV-I/R-16 adsorption and infectivity of target cells. Table 1 is a summary of HTLV-I/R-16 adsorption and attempted infection of human lymphoid target cells by cocultivation with HTLV–I producing donor cells. Table 1 is arranged in rank order of the highest to the lowest levels of HTLV-I/R-16 cellular adsorption. The data correlates directly with the transmission of HTLV-I to target cells by cocultivation with an equal number of irradiated, virus-positive T lymphoblasts. The MT-2, HUT 102-B2, MOLT 4, and normal adult-activated cycling PBMs bound HTLV-I/R-16 at mean fluorescence >10. The high relative mean fluorescence of HTLV-I/R-16 bound to HUT 102-B2 cells, is consistent with the high level of constitutive, endogenous infectious HTLV-I expression. Consequently, the amount of intracellular HTLV-I core antigen p19 detected by indirect immune fluorescent assay was equally elevated. Examination of chromosomal HTLV-I DNA by dot blot or Southern blot hybridization revealed intense dark dots or bands, indicative of multiple integrated copies of HTLV-I. In addition, virion-associated reverse transcriptase was detected with a specific template primer poly [rC]. • oligo [dG] in the presence of Mg^{2+}. MOLT 4, an immature T lymphoblast cell line, and normal activated adult mononuclear cells can be infected with HTLV-I, as indicated by results of similar virus transmission assays.[8] The adsorption of HTLV-I/R-16 to HUT 78, FR45, and NK41, is approximately sixfold less than that to HUT 102-B2 cells. Homologous untagged HTLV-I failed to interfere significantly with HTLV-I/R-16 bindings in this former cell group. These data suggested relatively fewer binding sites and a lack of affinity for HTLV-I binding sites, which correlates well with the lack of HTLV-I transmission.

Two nonlymphoid, nonhuman fibroblast cell lines tested in the same experiment with the human lymphoid cell lines were African green monkey kidney epithelioid cells (VERO) and wild mouse fibroblasts (SC-1). Both these cell types are large in comparison to fresh mature lymphoid cells. In agreement with this size correlation, SC-1 and VERO cells both had large numbers of HTLV-I/R-16 binding sites with relative mean fluorescence of 120 and 59, respectively (data not shown), which was reduced approximately twofold with an equal concentration of competitive homologous unlabeled HTLV-I. At present, no evidence of HTLV-I infectivity has

Table 1. Relationship Between HTLV-I Virus Adsorption and Infection in Human Lymphoid Cells

*Activated normal adult peripheral blood mononuclear cells from normal donors.

been observed, but to prove conclusively a lack of HTLV-I transmission cocultivated target cells should be screened in a more sensitive assay such as the polymerase chain reaction coupled with Southern blot hybridization. The adsorption of virus to cell membranes does not always imply that the cell is permissive for infection. Susceptibility of cells to infection can be controlled at later points in the virus growth cycle beyond virus penetration into the cell.

HTLV-I adsorption to normal human mononuclear targets. Four normal donors were screened for HTLV-I/R-16 binding sites on their Ficoll-Hypaque density-gradient–purified mononuclear cells before and after activation of their T lymphocytes with PHA and growth in partially purified, delectinated IL 2 (Table 2). All nonactivated mononuclear target cells bound HTLV-I/R-16 to form a single peak of fluorescent cells. In contrast, the activated target cells were separated in two peaks of fluorescent cells based on intensity. The nonactivated PBMs were significantly more resistant to competition with unlabeled homologous HTLV-I, suggesting a lack of specificity. In three of four donors, one activated peak was significantly higher and the other lower than the nonactivated fluorescent cells (Table 2). In donor 4, the HTLV-I/R-16–bound cells with the highest intensity of fluorescence after activation were not significantly higher than the single peak of nonactivated target cells. These results were in accord with earlier studies showing that HTLV-I infection of normal mononuclear cells is more efficient in cycling, activated cells.[8] Analysis of T-enriched *v* non-T–enriched populations from these mononuclear preparations indicates that HTLV-I adsorption is greatest in the former population (Fig 3B).

Table 2. HTLV-I/R-16 Adsorption to Nonactivated and PHA-Activated Normal PMB Target Cells

Donor	PHA*	Fluorescence† HTLV-I/R-16 Cell Bound
1	−	46
	+	21,75
2	−	46
	+	20,90
3	−	46
	+	19,91
4	−	90
	+	19,92

*Both PHA-activated and nonactivated target cells were analyzed in the same experiment on the same day. In the PHA(−) samples, Ficoll-Hypaque density-gradient–purified mononuclear cells were immediately used in the above experiment. In the PHA(+) samples, 5 μg/mL PHA was added to target cell cultures for 24 hours. The cells were washed and resuspended in fresh media with 20% partially purified, delectinated IL 2. At 6 days, the virus adsorption assay was performed.

†Data represent relative mean fluorescence.

Competitive binding of HTLV-II. Table 3 shows the results of cross-interference experiments between HTLV-I and HTLV-II in MT-2 and Mo-T cells initially adsorbed with one HTLV/R-16 and subsequently challenged with a homologous or heterologous HTLV/R-16. In MT-2 cells, HTLV-I/R-16 bound more effectively than HTLV-II/R-16, but the cross-interference patterns were very similar. HTLV-II blocked 66% of HTLV-I/R-16 binding, whereas HTLV-II inhibited 54% of its own adsorption. In Mo-T cells, constitutively producing HTLV-II, the number of HTLV-I binding sites was still higher than for HTLV-II. The homologous interference pattern of HTLV-II in Mo-T cells was slightly less than the homologous interference in MT-2 cells with HTLV-I.

DISCUSSION

In this report, a flow cytometric analysis used in previous Epstein-Barr virus (EBV) cell receptor studies[32] is described for investigation of HTLV-I specific binding to fresh and cultured cells on a single cell basis. This assay used rhoda-

Table 3. Competitive Binding of HTLV-II with HTLV-I

Target Cells	Competitive HTLV* Unlabeled	R-16-Labeled† HTLV	Relative Mean Fluorescence	Fluorescence Reduction (%)
MT-2	—	HTLV-I	66	—
MT-2	HTLV-I	HTLV-I	30	54
MT-2	HTLV-II	HTLV-I	22	66
MO-T	—	HTLV-I	47	—
MO-T	—	HTLV-II	12.5	—
MO-T	HTLV-II	HTLV-II	7.2	43

*Competitive unlabeled HTLV-I or HTLV-II at the same concentration as labeled virus were incubated at 4 °C for 2 hours followed by incubation with HTLV/R-16.

†HTLV-I or HTLV-II purified virions (50 pmoles of reverse transcriptase activity) were labeled with R-16 rhodamine hydrocarbon and incubated at 4 °C for 30 minutes with 7.5 × 10^5 target cells.

mine hydrocarbon-tagged, purified HTLV-I virions, according to the procedure originally published for avian retroviruses.[22,24] Automated detection of HTLV-I binding by flow cytometry permitted rapid, sensitive, and reproducible testing. Accurate quantitation of virus binding to single cells could be performed on as few as 10^4 cells. The rate of virus–cell binding was temperature dependent, characteristic of all virus–cell receptor interactions. Only a specific virus–cell interaction was detected because nonrhodamine-tagged, homologous HTLV-I interfered with HTLV-I/R-16 binding significantly in susceptible but not resistant target cells. In contrast, unrelated, nonlabeled retroviruses were unable to block HTLV-I/R-16 binding in HTLV-I–sensitive target cells. Moreover, several target cell lines were insensitive to HTLV-I/R-16 adsorption.

The existing knowledge regarding the HTLV-I and HTLV-II cell membrane receptors is scarce as opposed to that which is known regarding the unrelated HIV. In contrast, the nature of the HIV-I cell receptor has been identified as an epitope of the CD4+ cell surface phenotype which is characteristically found on normal helper T lymphocytes.[33,34] The HTLV-I and HTLV-II receptors, which are known to differ from HIV-I, are still a mystery, although their distribution has been studied by us and other researchers.[35-37] A summary of our studies in lymphoid and nonlymphoid cells follows. First, a direct relationship was shown between the expression of HTLV-I receptors on lymphoid targets and successful transmission of HTLV-I to the latter by cocultivation with irradiated, HTLV-I producing T lymphocytes. The target lymphoid cells are discussed in descending rank order of specific HTLV-I binding. As expected, HUT 102-B2 and MT-2, HTLV-I constitutively producing T lymphoblast cell lines expressed high levels of HTLV-I binding sites. This, in part, is a consequence of the relative large surface area of these cells. In reality, the number of binding sites may be much higher in these cells because some of the viral binding sites may be masked by previously bound, endogenous budding HTLV-I virions. These observations confirmed earlier studies using a fluoresceinated virus–cell binding assay analyzed on a flow cytometer.[35,36] MOLT 4, is the only immature T cell line identified with HTLV-I binding sites and susceptible to infection. This neoplastic cell line was derived from a patient with acute lymphocytic leukemia. Four other established human T cell leukemic cell lines were studied by Sinangil et al.[36] Two of four carried HTLV-I adsorption sites and were capable of HTLV-I infection. Weiss et al observed HTLV-I cell surface receptor on most T cell lines tested by an indirect VSV (HTLV) pseudotype infectivity assay.[15] Enhancement of HTLV-I binding sites in a subpopulation of the mononuclear targets was noted with mitogen activation and IL 2 stimulation of fresh adult PBMs as compared with nonactivated control PBMs. This pattern was observed in three of four samples tested and in complement studies by Merl et al,[8] who demonstrated that proliferating cycling T cells were more sensitive to HTLV-I transmission and subsequent transformation than were resting, nonstimulated T cells. Sinangil et al observed HTLV-I adsorption sites on fresh adult nonactivated T lymphocytes from a single donor by direct binding assays.[36] All other lymphoid cells examined (including HUT 78, a non–HTLV-I–producing lymphoblast cell line from a cutaneous T cell lymphoma patient; FR45, a continuous normal, EBV-positive B cell line; and NK41, a continuous normal NK T cell line) were relatively resistant to HTLV-I adsorption. These results suggest that the latter target cells either have very low or no HLTV-I binding sites. Our results with the HUT 78 T cells confirm an indirect VSV (HTLV-I) pseudotype transmission analysis.[15] Two other transformed B cell lines were examined previously.[36] The two Burkitt's lymphoma B cell lines, Loukes and Raji, were highly to moderately positive for expression of HTLV-I binding sites without a direct correlation with HTLV-I transmission.[36] Virus transmission may have proved successful if cocultivation with HTLV-I–producing T cells instead of cell-free virus infection had been used or if virus transmission had been examined at a much later time. An alternative explanation would be a postpenetration cellular restriction responsible for blockade of HTLV-I growth.

The relatedness of HTLV-I and HTLV-II envelope glycoproteins and their specific binding sites was also studied by us and by other researchers.[15,18] Sodroski et al compared the primary structure of the exterior spike glycoprotein of HTLV-I and HTLV-II.[18] The major glycoprotein of HTLV-I and HTLV-II showed 65% identity. Within the spike glycoprotein, similarity between the regions of hydrophilicity and hydrophobicity, glycosylation sites, and the location of cysteine residues suggested common secondary and tertiary structures.[18] In addition, limited interference and cross-neutralization of VSV (HTLV-I) and VSV (HTLV-II) pseudotypes were observed,[15] indicating that the envelopes of HTLV-I and HTLV-II are similar but antigenically distinct. Weiss and co-workers studied the relatedness of HTLV-I and HTLV-II envelope glycoprotein cell membrane receptor sites. Both viruses appear to recognize the same receptors, as shown by receptor interference of syncytium induction (cell fusion) and pseudotype infectivity, but HTLV-II induced cell syncytia in a more restricted host cell range.[15] Other differences also existed. Indeed, HTLV-I could be grown in a number of nonlymphoid cell types, whereas attempts to propagate HTLV-II in the same cells were unsuccessful.[15]

The above findings were confirmed here by direct virus-cell binding analyses on the flow cytometer. HTLV-II was highly competitive with HTLV-I for MT-2–specific virus binding sites. HTLV-II bound fewer specific adsorption sites than did HTLV-I. This difference may reflect the difference in adsorption time of the nonlabeled and labeled virus and/or a lesser affinity of HLTV-II for the same receptor sites. Furthermore, there was more HTLV-I and HTLV-II specific adsorption of MT-2 cells than of Mo-T cells, neoplastic T lymphoblasts constitutively releasing HTLV-II. These observations correlate with the fact that MT-2 cells possess more integrated proviral HTLV copies and a faster growth rate than does Mo-T.

In two nonlymphoid, nonhuman cell lines, a direct correlation between HTLV-I adsorption sites and HTLV-I infection could not be established. The cell lines, African green monkey kidney cells (VERO) and wild mouse fibroblasts

(SC-1) bound high levels of HTLV-I virions, but viral transmission was not successful. These data directly indicate the presence of HTLV-I receptors. An indirect pseudotype infectivity assay and syncytia formation assay with T cells producing HTLV-I of 15 different nonlymphoid cells (including VERO) indirectly suggested the same conclusion.[37] These studies suggested that HTLV-I receptors were present on all cells capable of VSV (HTLV-I) pseudotype propagation or cell fusion. Therefore, in nonhuman, nonlymphoid cell cultures, the cellular receptor restriction was not the major determinant of cell tropism of HTLV-I. In conclusion, our findings and further extended studies may lead to a clearer understanding of host susceptibility to disease, the pathogenesis of HTLV-I–induced ATL, and possible modification of host receptors for disease prevention.

Separation of Human Plasma Factor IX From HTLV-I or HIV by Immunoaffinity Chromatography Using Conformation-Specific Antibodies

By Steven A. Limentani, Barbara C. Furie, Bernard J. Poiesz, Richard Montagna, Keith Wells, and Bruce Furie

Immunoaffinity chromatography using conformation-specific antibodies yields pure factor IX from human plasma in a single rapid, facile purification step. We evaluated this technique to determine whether factor IX can be separated from human T cell leukemia virus-I (HTLV-I) and human immunodeficiency virus (HIV) in plasma supplemented with these viruses. Viral content was determined with an enzyme-linked immunosorbent (ELISA) assay sensitive to 50 ng viral protein. Both HTLV-I and HIV coeluted with unbound protein. Neither HTLV-I nor HIV was detected in purified factor IX. We conclude that, to the limits of detection, factor IX purified by this method is free of viral contamination.

© 1987 by Grune & Stratton, Inc.

HEMOPHILIA B is a sex-linked disorder characterized by a functional or quantitative deficiency of factor IX.[1-4] Bleeding episodes are treated with factor IX concentrates containing intermediate purity factor IX.[5-10] These agents are associated with complications, including disseminated intravascular coagulation, thrombotic disorders, hepatitis B, non A-non B hepatitis, and AIDS.[11-26] Currently, factor IX concentrates are heat treated to eliminate human immunodeficiency virus (HIV). Although this method may be effective in reducing HIV, definitive data on the role of heat treatment in preventing AIDS in hemophiliac patients awaits additional epidemiologic data. Furthermore, heat treatment results in the loss of 8% to 40% of the factor IX coagulant activity.[27-34]

We have described a method for the rapid, one-step purification of factor IX from plasma.[35] Antibodies specific for the metal-stabilized conformation of factor IX are used to bind factor IX to an insoluble support. Factor IX is dissociated from the antibodies by the addition of EDTA and the conversion of factor IX to its metal-free conformation.[35] The factor IX isolated by this method is homogeneous and has a specific activity of 120 to 150 U/mg. Furthermore, the factor IX isolated from plasma contaminated with hepatitis B virus yields factor IX free of measurable virus.[35] The purpose of the current study was to determine whether immunoaffinity chromatography using conformation-specific antibodies separates factor IX from HTLV-I or HIV.

MATERIALS AND METHODS

Preparation of HTLV-I and HIV. HTLV-I was produced from the cell line HUT 102 B2,[36] and HIV was produced from the B cell line FCRC-15/AAV.[37] Normal pooled human plasma was obtained from donors who were negative for HTLV-I and HIV antibody and antigen.[36-39] Purified HTLV-I and HIV were prepared by centrifugation (45,000 g) of cell-free conditioned media from the respective cell lines.[36] Pelleted particles were sedimented on alternating discontinuous glycerol (30% over 100% cushion), continuous sucrose (22% to 65%), and discontinuous glycerol (30% over 100% cushion) gradients. Positive fractions were identified by assaying reverse transcriptase activity using the template primer poly (C) oligo dG in the presence of 10 mmol/L $MgCl_2$.

Competitive enzyme-linked immunosorbent assay (ELISA) for HTLV-I and HIV. Polyclonal rabbit anti–HTLV-I and anti-HIV antibodies were raised in rabbits immunized with ether-disrupted purified virions, and the antibodies were measured by ELISA and Western blot assays for HTLV-I and HIV antibodies.[38] Microtiter plates were coated with 200 ng viral protein (either HTLV-I or HIV) in 100 μL CBC (150 mmol/L Na_2CO_3; 350 mmol/L $NaHCO_3$,pH 9.6) and then incubated overnight at 4°C. After incubation, excess solution was removed and 100 μL of 1% bovine serum albumin (BSA) in CBC was added to each well; the plate was incubated overnight at 4°C.

Dilutions of rabbit antisera ($^1/_{60}$ for HTLV-I and $^1/_{5,000}$ for HIV) were made in phosphate-buffered saline (PBS)-Tween 20. Competing proteins and diluted antisera were incubated together for 1 hour at 23°C. The viral protein-coated wells were washed three times with 0.1% BSA in PBS-Tween 20 and then 100 μL of the antiserum mixture described above were added to the appropriate well. After incubation for 1 hour at 23°C, the plates were washed three times with PBS-Tween 20 and 100 μL of goat anti-rabbit IgG alkaline phosphatase conjugate (1/5,000 dilution in PBS-Tween 20) was added. The plates were incubated for 2 hours at 23°C, washed three times with PBS-Tween 20, and 100 μL of *p*-nitrophenyl phosphate was added to each well. The plates were developed for 30 minutes, and the reaction was stopped with 15 μL of 3 N NaOH. The plates were read at 405 nm.

Preparation of anti-factor IX:Mg(II) antibodies. Antibodies were isolated as previously described, except that a subpopulation of conformation-specific antibodies were used that bind to factor IX in the presence of Mg^{2+}. Antibodies that bind to factor IX in the presence of Ca^{2+} but not Mg^{2+} were removed.[40] Rabbit anti-factor IX:Mg(II) antibodies were coupled to cyanogen bromide-activated Sepharose 4B at a concentration of 2.5 mg/mL Sepharose.[41] In the experiment with HIV, factor IX was isolated on the anti-factor IX:Mg(II) antibody–Sepharose column.[40] An anti-factor IX:Ca(II)–Sepharose column was used in the experiment with HTLV-I; this column has been previously described.[35]

Isolation of factor IX from virus-supplemented plasma with anti-factor IX:Mg(II) Sepharose. Pooled human plasma (100 mL) was dialyzed overnight against 0.05 mol/L Tris-HCl, pH 7.4, 0.5 mol/L NaCl. After dialysis, the plasma was adjusted to 7.5 mmol/L

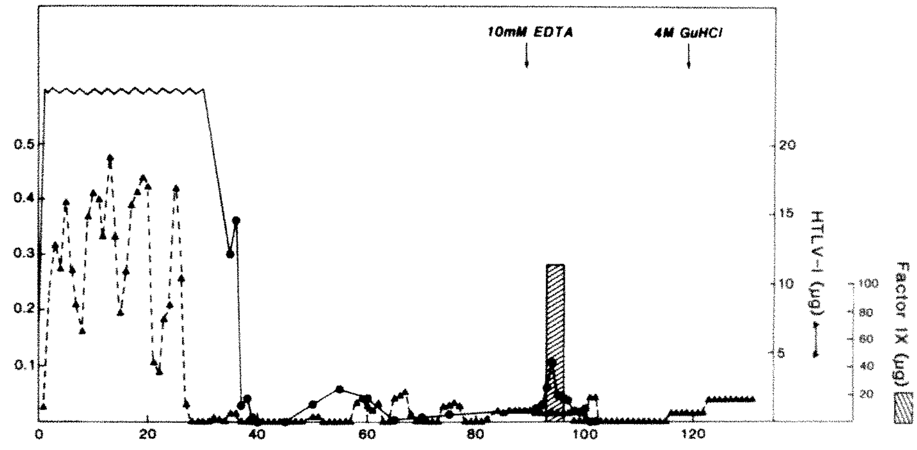

Fig 1. Purification of human factor IX from plasma contaminated with HTLV-I. Elution of protein was evaluated by absorption at 280 nm (●). Elution of HTLV-I was measured using an ELISA directed against the viral coat protein (▲). Elution of human factor IX was assayed by a radioimmunoassay; the total factor IX contained in the pooled fractions is shown (hatched columns).

with 1 mol/L $MgCl_2$. Then either 500 μg of HTLV-I or 500 μg of HIV was added to the plasma. As a control, an equal volume of plasma without added viruses was applied to the affinity column to assess nonspecific background in both the HTLV-I and the HIV assays. The column was developed as previously described except that Tween-20 was added to buffers only in the experiment in which HTLV-I was added to plasma. The flow-through was collected in 5.5-mL fractions initially and then 1.5-mL fractions during elution of factor IX with 10 mmol/L EDTA. The protein concentration was estimated by the absorption at 280 nm and by factor IX radioimmunoassay. Pooled fractions were subjected to high-speed centrifugation (49,000 g) for 60 minutes. The pellets were disrupted with ether and resuspended in 100 μL of PBS-Tween-20. Ten microliters were then assayed for HTLV-I or HIV.

RESULTS

Evaluation of viral content of affinity-purified factor IX. HTLV-I (500 μg) was added to pooled human plasma prior to isolating factor IX on the anti-factor IX:Ca(II)–Sepharose column. HTLV-I coeluted with unbound protein. No HTLV-I was detected in the material that was eluted from the column with either EDTA or guanidine HCl (Fig 1). By this analysis, a minimum of a 1,000-fold reduction in HTLV-I occurred in face of a 10,000-fold increase in the specific activity of factor IX.

In a separate experiment, HIV (500 μg) was added to pooled plasma prior to the application of the plasma to the anti-factor IX:Mg(II)–Sepharose column. The HIV coeluted with unbound protein. No viral contamination was detected in the material eluted from the column with either EDTA or guanidine HCl (Fig 2). As previously, a minimum of a 1,000-fold reduction in HIV occurred in face of a 10,000-fold increase in the specific activity of factor IX.

The standard curves for the competitive ELISA demonstrated a sensitivity to 50 ng viral protein (Fig 3). Pooled human plasma without endogenous or added viral contaminants was applied to the anti-factor IX:Mg(II)–Sepharose column. The unbound and bound fractions obtained from this experiment were assayed for HTLV-I and HIV to determine accurately the level of nonspecific binding in the assay. The OD_{405} values observed were equivalent to the OD_{405} values observed in the factor IX prepared from experimentally contaminated plasma samples.

DISCUSSION

This study examined the behavior of two of the human retroviruses, HTLV-I and HIV, when they are present in plasma used for purification of factor IX. Our data indicate that, to the limits of detection of the immunoassay systems used, these viruses do not copurify with factor IX. The virus

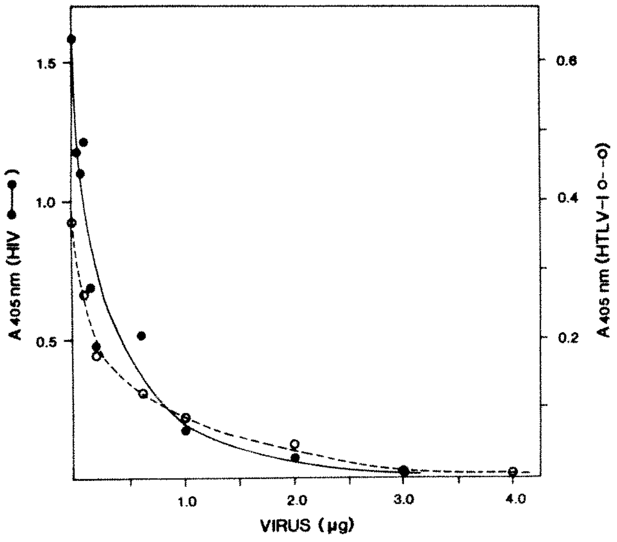

Fig 3. ELISA systems for quantitation of viral proteins from HTLV-I or HIV. HIV (●——●), HTLV-I (○——○).

and the factor IX that is eluted with EDTA are resolved. Our data from these and earlier experiments indicate a general method for the separation of factor IX from viruses using an immunoaffinity purification involving specific binding and specific elution.

The morbidity associated with infusion of currently available factor IX concentrates has been well described. Recent epidemiologic data on the development of the acquired immunodeficiency syndrome in patients with hemophilia are of great concern.[23-26] Thirty percent to 36% of the patients treated with factor IX concentrate showed HIV antibody positivity.[23,24] Lyophilization of factor IX concentrates results in a 10- to 100-fold decrease in virus.[30,34] Heat treatment of factor IX concentrates for 20 hours at 60°C renders HIV undetectable.[27,34] Assumptions regarding the complete sterilization of factor IX concentrates from HIV contamination are done by extrapolation of the data derived from immunoassays.[34] A small group of hemophilia A patients whose sera were initially negative for anti-HIV antibodies have received heat-treated factor VIII concentrate for up to 1 year without seroconverting.[29] This suggests marked improvement can be anticipated in treatment of hemophilia B patients with heat-treated factor IX concentrate. Heat treatment, however, results in the loss of ~8% to 40% of the factor IX coagulant activity of the factor IX concentrate.[32,34]

Our technique provides a rapid, one-step quantitative purification of homogeneous factor IX. We showed that, to the limits of detection, the factor IX isolated by this method is free of retrovirus, even when these viruses are added in high titer to plasma. These results indicate that this immunoaffinity method might be integrated into methods of manufacture of factor IX used for the treatment of hemophilia B. Whether this method can eliminate the need for heat treatment of plasma to eliminate HIV or render the factor IX free of hepatitis viruses will require direct infectivity assays or systematic study of patients treated with this new preparation.

Flow Cytometric Analysis of Human Bone Marrow. II. Normal B Lymphocyte Development

By Michael R. Loken, Virendra O. Shah, Karen L. Dattilio, and Curt I. Civin

A panel of B lymphoid-reactive monoclonal antibodies was used to analyze the phenotypic changes that accompany B lymphocyte development in normal human bone marrow. The B lymphoid cells were identified using light scattering and the expression of CD19 on a flow cytometer. Quantitative three-color immunofluorescence was then used to correlate other cell surface antigens on these cells identified as B lymphoid in normal marrow. CD10 and CD20 identified almost exclusive populations and provided a convenient means of discriminating between the less and more mature B lineage cells. The CD10^{+} cells could be further subdivided using CD34. The population of CD19^{+}, CD10^{+}, CD34^{+} cells comprised only 0.6% of marrow cells, but these contained the majority of terminal deoxynucleotidyl transferase (TdT^{+}) cells. In the assessment of class II antigens, HLA-DR was expressed on all B lineage cells whereas HLA-DP preceded HLA-DQ in appearance during the developmental process. Among the later antigens expressed on B lineage cells, cell surface IgM, CD20, and HLA-DQ were expressed at essentially the same time. Cell surface CD10 was lost at the time when CD21 and CD22 were acquired on the cell surface. These data illustrate that multiparameter flow cytometry can be used to define a continuous progression of stages of B lymphocyte development based on cell surface antigen expression even though these cells represent a minor fraction of normal marrow cells.

THE BONE MARROW is the site of production and early maturation of B lymphocytes in humans.[1] A correlation between maturational stage and cell surface antigen expression of B lymphocytes has been made, primarily on the basis of cell surface phenotypes of acute lymphoblastic leukemias (ALL) and lymphomas.[2-4] Counterparts of many of the malignant cells have been identified in normal bone marrow.[1,5-7]

Previous studies of B lymphocyte surface antigens have identified CD19 (Leu-12, B4) as a marker for all B lymphocytes.[8,9] CD19 is expressed very early in B cell development and is retained until the latest stages of cell activation and antibody secretion.[8] This marker is expressed on most non-T ALL (>95%), but is not found on T cell ALL or on myeloid lineage leukemias.[2,3] Thus, CD19 defines most cells of the B lineage with exceptional lineage specificity.[2]

Another B cell antigen, CD20 (Leu-16, B1), is expressed later during B lymphocyte development.[10,11] As compared with CD19, CD20 is expressed on fewer normal B lymphocytes in the marrow and on a lower percentage of leukemias.[2,3,10,11] CD10 (common ALL antigen, CALLA, J5) has been found on most cases of non-T ALL but is expressed on only a subset of immature B lymphocytes.[2,12,13] Mature peripheral blood B lymphocytes express both CD19 and CD20, but do not express CD10.[10,12] The progenitor cell-associated antigen, CD34 (My10) is also observed on some B lineage ALL cases, but is not expressed on normal peripheral blood B cells.[14]

Mature B lymphocytes in peripheral blood express class II antigens including HLA-DR, HLA-DP, and HLA-DQ, as well as several other B lymphocyte specific antigens: CD21 (CR$_2$), CD22 (Leu-14), cell surface IgM (sIgM), and IgD (sIgD).[15-19]

In this article, we correlate the expression of multiple cell surface markers on normal bone marrow B lineage cells. By using multiparameter quantitative analysis on a flow cytometer, we examined all low-buoyant-density cells obtained from the bone marrow sample without preenrichment. The entire B lymphoid lineage was identifiable using CD19 in combination with light-scattering characteristics. Pairs of other cell surface antigens were then identified and correlated on the CD19^{+} cells by using three-color immunofluorescence.[20] From these data in combination with cell sorting and immunostaining for terminal deoxynucleotidyl transferase (TdT), we could define the sequence of appearance during B lymphocyte development of these antigens: HLA-DR, HLA-DP, HLA-DQ, CD10, CD19, CD20, CD21, CD22, CD34, sIgM, sIgD, and nuclear TdT.

MATERIALS AND METHODS

Monoclonal antibodies. Fluorescein-conjugated (FITC) and/or phycoerythrin (PE)-conjugated CD3(Leu-4), CD10(CALLA), CD11b(Leu-15), CD14(Leu-M3), CD16(Leu-11), CD19(Leu-12), CD20(Leu-16), CD21(CR$_2$), CD22(Leu-14), anti-HLA-DR, anti-HLA-DP, anti-HLA-DQ, streptavidin allophycocyanin (APC) along with purified CD34(HPCA-1) were obtained from Becton Dickinson Monoclonal Center, Mountain View, CA. Anti-glycophorin (10F7) was a kind gift from Dr R. Langlois (Lawrence Livermore National Laboratory, Livermore, CA) CD19(Leu-12) and CD10(CALLA) (Becton Dickinson) were coupled with biotin, following the protocol of Billingsley.[21] Anti-human IgM-FITC, anti-human IgD-FITC and F(ab')$_2$-goat anti-mouse Ig-FITC were obtained from Tago, Burlingame, CA.

Cell preparation and immunofluorescence. Bone marrow aspirates were obtained from consenting normal adult volunteers. Collection of samples was performed after being approved by the Institutional Review Board, as approved by the Department of Health and Human Services. The low-density leukocytes (1.077 g/cm^3, Ficoll-Hypaque, Pharmacia, Piscataway, NJ) were washed

Blood, Vol 70, No 5 (November), 1987: pp 1316-1324

in RPMI 1640 containing 10% fetal bovine serum (FBS) and aliquoted for immunofluorescent staining. The cells were suspended at a concentration of 10^7/mL. In the experiments in which both antibodies were directly conjugated to the fluorochrome, the first antibody was added to 10^6 cells using an amount of antibody that gave maximal fluorescence. The cells were incubated on ice for 20 minutes. The cells were then pelleted and washed with buffer (at least five times the staining volume) before the second antibody was added. After 20 minutes on ice, the cells were again washed with buffer.

For three-color analysis, cells were reacted with FITC-conjugated, PE-conjugated, and biotin-conjugated antibodies for 20 minutes and were then washed. APC-conjugated streptavidin was then added, and the cells were incubated for an additional 20 minutes and washed and fixed in 1% paraformaldehyde.

Three-color analysis using CD34 was performed as follows: Cells were incubated with CD34 on ice for 20 minutes, washed and incubated with $F(ab')_2$ goat anti-mouse Ig for 20 minutes, and washed. Cells were further incubated with 10% normal mouse serum to block any free binding sites of the second step antibody. After being washed, the cells were reacted with PE-conjugated and biotin-conjugated antibodies, followed by the APC-conjugated streptavidin. Unstained cells, IgG1-FITC, IgG2-PE, and cells labeled with streptavidin-APC but without biotin conjugate were included as controls.

Flow cytometry. Quantitative fluorescence analysis was performed using a five-parameter FACS 440 (Becton Dickinson Immunocytometry Systems). The optical configuration and filter combinations for three-color immunofluorescence using FITC, PE, and APC have been described previously.[20,22] The argon-ion laser was operated at 488 nm using 200 mW of power. FITC emissions were collected with a 530/30 bandpass (BP) filter, and PE emissions were collected with a 585/42 BP filter. The laser beam was focused using a 2-inch focal length spherical lens. Three-color immunofluorescence was performed using HeNe laser of 633 nm, 40 mW, together with an argon laser as described.[23] APC emission was collected with a 660/20 BP filter. Fluorescence signals were processed using a four-decade logarithmic amplifier. Light scattering signals were processed by linear amplification.

A minimum of 30,000 events for each sample was collected in list mode on a Consort 30 Data Management System, Becton Dickinson. This permitted reanalysis of the data to demontrate the correlation between three colors of immunofluorescence for populations of cells identified by forward-angle and right-angle light scattering. In the assessment of class II and later B lymphoid antigens of the marrow B lineage cells, the data were pregated on light scattering and CD19 fluorescence. The contour lines in Figs 1 through 7 were drawn at levels of 2, 4, 8, 16, 32, 64, and 128. The fluorescence correlations in Figs 2 through 7 were gated on the light-scattering window depicted in Fig 1A.

Cell sorting. Viable cells, stained for two colors of immunofluorescence, were sorted based on the gates indicated in the appropriate Figs. Replicate cytocentrifuge slides were prepared for each sorted fraction of cells. These slides were coded, stained for nuclear TdT (rabbit anti-TdT, a kind gift from Dr F. Bollum) using an immunoperoxidase procedure (Supertechs, Bethesda, MD) or Wright's, and differential counts were made for each sample.[24]

RESULTS

Bone marrow B lymphocytes have distinctive light-scattering properties. Normal human bone marrow cells were heterogeneous in their forward- and right-angle light-scattering characteristics (Fig 1A). The $CD19^+$ B cells were confined to a well-defined cluster, which was previously classified as "lymphoid" (Fig 1B) with low-to-moderate forward-angle and low right-angle light-scattering properties.[25] All subsequent multicolor immunofluorescence analyses were performed by gating on this light-scattering population, as shown in the box in Fig 1A. More than 95% of the $CD19^+$ cells in whole ungated marrow were included within this gate.

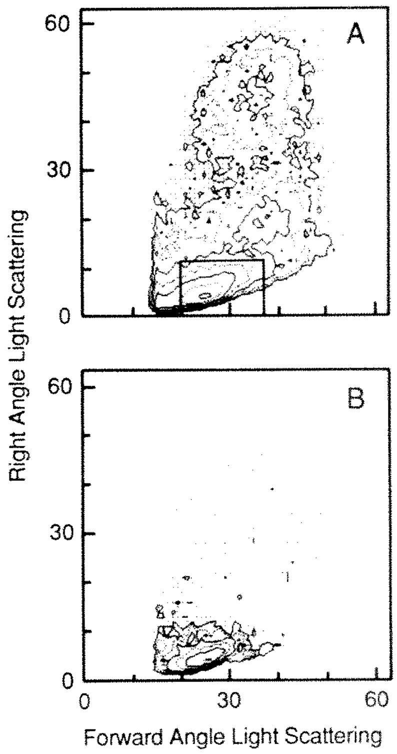

Fig 1. The correlation between forward- and right-angle light-scattering for (A) all low-buoyant-density bone marrow cells and (B) the CD19/Leu-12$^+$ B lineage cells. The box in A identifies the gate used to reanalyze the list mode data. This gate included >95% of all CD19$^+$ cells. A minimum of 30,000 events were collected for each list mode file.

We used two-color immunofluorescence to confirm that CD19 bound only to B lineage cells and not to cells of other lineages in normal human bone marrow. Normal marrow cells were reacted with CD19 in combination with either CD3 (T cells), CD16 (natural killer [NK] and neutrophils), CD14 (monocytes), CD11b (NK, monocytes and neutrophils), or anti-glycophorin (erythroid cells).[26-30] Quantitative fluorescence analysis on the flow cytometer demonstrated that the cells labeled with CD19 were not double labeled with the other antibodies (data not shown); thus, CD19 and the other antibodies identified mutually exclusive cell populations in bone marrow.

CD20 and CD10 define distinct stages of B lymphocyte development. The CD20 antigen is expressed late during B lymphocyte development, whereas CD10 has been associated with early B lymphocytes.[10-13] To define more precisely when, during development, B lymphocytes lose CD10 and acquire CD20, we performed three-color immunofluorescence experiments using CD10 and CD20 in correlation with CD19.

The two-color correlated expression of CD20 and CD19

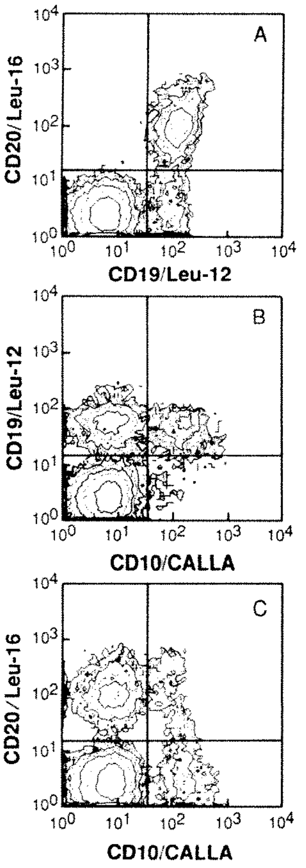

Fig 2. Three-color immunofluorescence analysis of bone marrow cells labeled with CD19/Leu-12 PE, CD20/Leu-16 FITC, and CD10/CALLA biotin (APC-streptavidin). Correlations were made between (A) CD19 and CD20, (B) CD19 and CD10, and (C) CD10 and CD20. All data were gated on the light-scattering window in Fig 1A. Although both the CD20$^+$ and the CD10$^+$ cells were also CD19$^+$ (A, B), they identified almost completely non-overlapping populations (C). The quadrants were set using appropriate negative controls.

on marrow cells (Fig 2A) confirmed that CD20 was expressed on a subset of the CD19$^+$ cells; all CD20$^+$ cells were also CD19$^+$. No CD20$^+$ cells were outside the lymphoid light scattering window.

CD10 was also found on a portion of the CD19$^+$ cells (Fig 2B). CD10$^+$, CD19$^-$ marrow cells were identified but these cells fell outside the lymphoid light-scattering window and were granulocytes (data not shown).

The correlation between CD20 and CD10 (Fig 2C) indicated that these two antibodies identified almost non-overlapping B lymphoid subpopulations: Most CD20$^+$ cells did not express CD10 and vice versa. A small subset of cells, however, expressed both markers. The proportions of cells within marrow that expressed CD19, CD20, and CD10 are presented in Table 1. CD19 stained ~6.5% of all marrow cells, whereas CD20 labeled ~4.5%. A slightly smaller proportion of marrow cells, 3.5%, were CD10$^+$. Of the CD19$^+$ B cells in marrow, ~60% expressed CD20, whereas only 40% expressed CD10. Only ~20% of the CD20$^+$ cells were also CD10$^+$, and a similar proportion of all the CD10$^+$ cells in this light-scattering window were double labeled with CD20. Together, CD10 and CD20 identify almost all CD19$^+$ B lineage cells. A few marrow B lineage cells (<5% of CD19$^+$ cells) lack both CD10 and CD20, a phenotype consistent with plasma cells.

Early marrow B lineage cells co-express CD19, CD10, and CD34. CD34 was expressed on a subset of B lineage ALL cases as well as on a small population of immature normal marrow cells, including all in vitro assayed hematopoietic progenitor cells, but was not expressed on mature normal cells.[14] All TdT$^+$ cells in normal marrow were previously found in the CD34$^+$ fraction.[31] Because TdT expression is a characteristic of early lymphoid cells, we used three-color immunofluorescence to investigate whether the B cell antigens identified by CD19 and CD10 could be found on any CD34$^+$ cells.

In the correlation between CD19 and CD34, a small population of dim CD19$^+$ cells was also labeled with CD34 (Fig 3A). Most of the CD19$^+$ cells, however, were negative for the CD34 marker (Table 2). Less than one-half of the CD34$^+$ cells were CD19$^+$.

In a similar correlation between CD10 and CD34, a population of cells was double labeled. The cells that were most intensely stained with CD10 were the cells that also bound CD34 (Fig 3B). In three-color experiments, these few CD10$^+$, CD34$^+$ cells were the ones that also expressed low amounts of CD19 (Fig 3A). These CD34$^+$, dim CD19$^+$, bright CD10$^+$ cells constituted <1% of total marrow cells (Table 2).

To characterize this minor cell population further, marrow cells were reacted with either (a) CD34 and CD19, or (b) CD34 and CD10. The cell subpopulations identified were then (FACS) sorted, and cytocentrifuge slides were prepared from the sorted fractions (Fig 3A and B shows sorting windows). These slides were examined for morphology (Wright's stain) or for nuclear TdT expression[24,31] (Table 3).

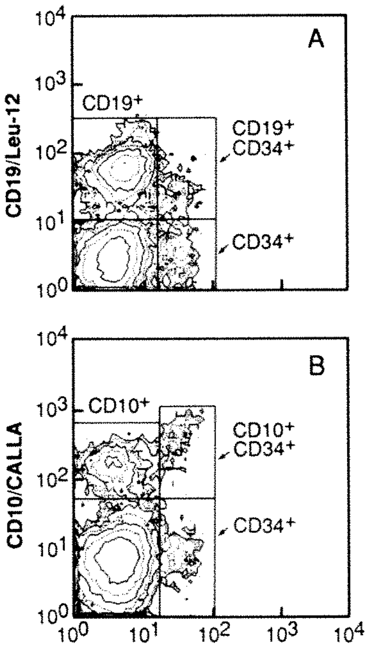

Fig 3. Immunofluorescence analysis of bone marrow cells labeled with CD34/HPCA-1 and either CD19/Leu-12 or CD10/CALLA. (A) The correlation between CD19 and CD34 indicates that a few double-labeled cells were identified. (B) A similar correlation between CD10 and CD34 also showed a double-labeled population of cells. Boxes in A and B illustrate the windows used for sorting the cell populations assessed for morphology and TdT expression (Table 3).

The most immature cells by morphology were in the CD34$^+$, CD19$^-$, CD10$^-$ fraction. This population contained many "undifferentiated" blast cells, without definite lymphoid features. A minor percentage of these cells stained perceptibly for intranuclear TdT. The double-labeled CD34$^+$, CD10$^+$ or the CD34$^+$, CD19$^+$ cells were somewhat more mature by morphology and could be characterized as lymphoblasts or lymphocytes. Most of these cells were intensely labeled (intranuclear pattern) with the TdT stain (Table 3). In contrast, the CD34$^-$, CD10$^+$, or CD34$^-$, CD19$^+$ cells contained a greater number of mature lymphocytes recognized by morphology that were negative for TdT staining.

The cells that did not stain with either set of antibodies (ie, double negative, CD34$^-$, CD10$^-$; or CD34$^-$, CD19$^-$) were a mixture of lymphocytes and developing erythroid cells from the middle to late normoblast stage.[25] These cells did not contain detectable intranuclear TdT.

*Cells of each phenotype (Fig 3) were sorted and cytocentrifuge slides were prepared.

†Cytocentrifuge slides were stained for nuclear TdT as described in the Materials and Methods section.

‡Replicate slides were Wright's-stained and examined for morphology. The predominant morphological type is given first for each category. When blast cells with definite lymphoid features were observed, these were enumerated. Furthermore, morphological distinction among blast cells was not attempted.

§Two complete experiments were performed.

To determine whether CD10 was expressed before CD19 on these early B lineage cells, the correlation of these two antigens on only the CD34$^+$ cells was determined (Fig 4). Although a few cells (~0.1%) expressed CD34 and CD10 without CD19, an equivalent number were identified expressing CD34 and CD19 without CD10 (Fig 4B). Three replicate experiments gave the same results with no clear evidence for either CD10 or CD19 to precede the other on the CD34$^+$ cells.

HLA-DR, HLA-DP, HLA-DQ class II antigens are sequentially expressed during B lymphocyte development. Two-color immunofluorescence studies have shown that normal marrow CD34$^+$ cells express low but detectable amounts of HLA-DR.[32] Quantitative studies of HLA-DR on B cells in comparison to the CD34$^+$ cells indicated that the amount of HLA-DR expressed on the (average) CD19$^+$ cell was approximately four times greater than that on the (average) CD34$^+$ cell (Fig 5). All the CD10$^+$ lymphoid cells expressed HLA-DR, although the brightest CD10$^+$ cells (ie, the CD34$^+$, bright CD10$^+$ from above) were less intensely labeled with HLA-DR than were most CD10$^+$ cells.

Three-color immunofluorescence was used to detect the acquisition of two other class II antigens: HLA-DP and HLA-DQ on marrow B lymphoid cells.[15,16] Marrow cells were labeled with CD19, CD10, and either anti–HLA-DP or anti–HLA-DQ. By gating on the CD19$^+$ cells, the correlation between CD10 and the class II antigens was assessed solely on the CD19$^+$ B lymphocytes without contamination

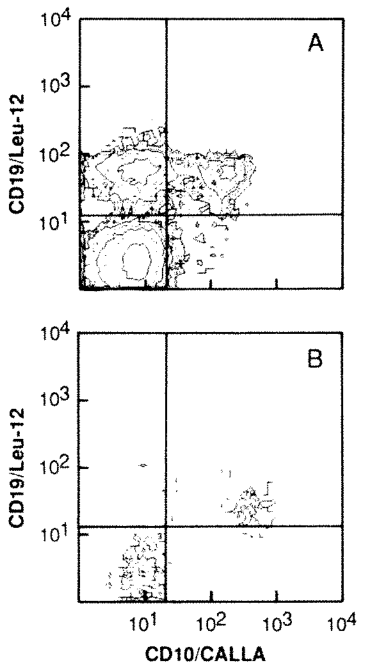

Fig 4. Three-color fluorescence analysis of bone marrow cells labeled with CD19, CD10, and CD34. (A) Correlation between CD19 and CD10 gated on the $CD34^-$ lymphocytes. (B) Correlation between CD19 and CD10 gated on the $CD34^+$ lymphocytes. (The composite ungated display shown in Fig 2B can be compared.)

of other cell types. (Additional class II-bearing cells were identified outside the light-scattering window in Fig 1A, since HLA-DR, HLA-DP, and HLA-DQ also labeled blasts and monocytes within the marrow.) A comparison between Fig 6A and C indicates that HLA-DP was expressed on almost all B lymphocytes, including the $CD10^+$ cells, whereas HLA-DQ stained mainly the $CD10^-$ B lymphocytes. The brightest $CD10^+$ cells (again corresponding to the $CD34^+$, $CD10^+$ cells shown above) lacked both HLA-DP and HLA-DQ.

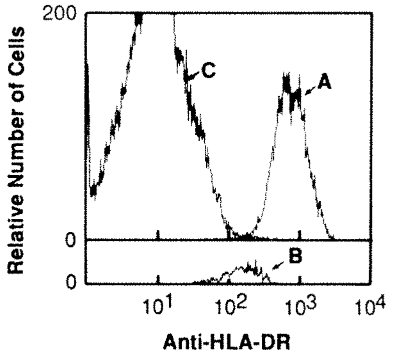

Fig 5. Intensity of HLA-DR expression on lymphoid populations in bone marrow. (A) Histogram of HLA-DR fluorescence gated on $CD19^+$ lymphocytes. This gate includes the $CD10^+$ and $CD20^+$ but not the $CD34^+$ cells. (B) HLA-DR fluorescence histogram gated on the $CD10^+$ bright, $CD34^+$ cells. The axes for this curve have been shifted down to show this minor population of cells on the same relative vertical scale. These cells constitute ~10% of all $CD19^+$ cells in the marrow and express approximately four times less HLA-DR. The remainder of the $CD34^+$ cells also express this lower HLA-DR intensity.[32] (C) Histogram of HLA-DR reactivity on the $CD19^-$ lymphocytes identified by light scatter in the marrow.

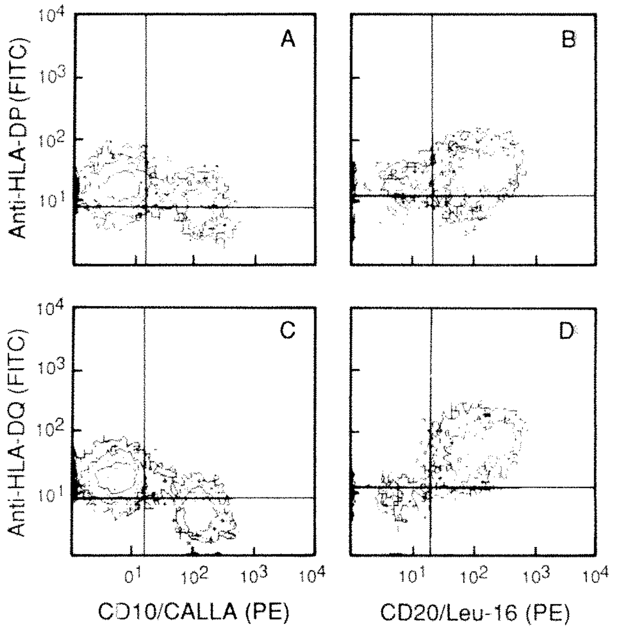

Fig 6. Analysis of class II antigens on marrow B lineage cells. B lineage cells were identified using light scattering and CD19/Leu-12 biotin (APC streptavidin). Only the $CD19^+$ cells (30,000 gated events) were then examined for the correlation between (A) anti–HLA-DP FITC and CD10/CALLA PE, (B) anti–HLA-DP FITC and CD20/Leu-16 PE, (C) anti–HLA-DQ FITC and CD10/CALLA PE, and (D) anti–HLA-DQ FITC and CD20/Leu-16 PE. Quadrants were set using appropriate negative controls.

In reciprocal experiments, marrow cells were labeled with CD19, CD20, and either anti–HLA-DP or anti–HLA-DQ to assess class II expression on more mature marrow B cells. In relating the CD20 with class II antigens on only the $CD19^+$ B lineage cells (Fig 6B and D), HLA-DP reacted with some B lineage cells that were $CD20^-$. (These cells were $CD10^+$, as shown in Fig 6A.) When CD20 and HLA-DQ were compared on the $CD19^+$ cells (Fig 6D), all $CD20^+$ cells were also $HLA\text{-}DQ^+$ and vice versa.

Later stages of B lymphocyte development are defined by CD20, CD22, CD21, sIgM, and sIgD. We used three-color immunofluorescence to study the expression of other cell surface markers on these $CD19^+$ marrow B lineage cells in a pairwise fashion. The data from 1 of 12 similar experiments yielding identical results are shown in Fig 7. Comparing CD20 and sIgM on the $CD19^+$ cells, we found that these two markers identified the same populations (Fig 7A). However, in a correlation between CD20 and sIgD, a significant population of $CD20^+$, $sIgD^-$ cells was identified in addition to the $CD20^+$, $sIgD^+$ cells (Fig 7B).

In the correlation of CD20 with CD22 (Fig 7C), there was a population of $CD20^+$, $CD22^-$ cells, in addition to the $CD20^+$, $CD22^+$ cell population. Likewise, there was a significant $CD20^+$, $CD21^-$ population in addition to a population of $CD20^+$, $CD21^+$ cells (Fig 7I). There were clearly more B lineage cells in the marrow labeled with CD20 than were reactive with antibodies detecting sIgD, CD21, or CD22.

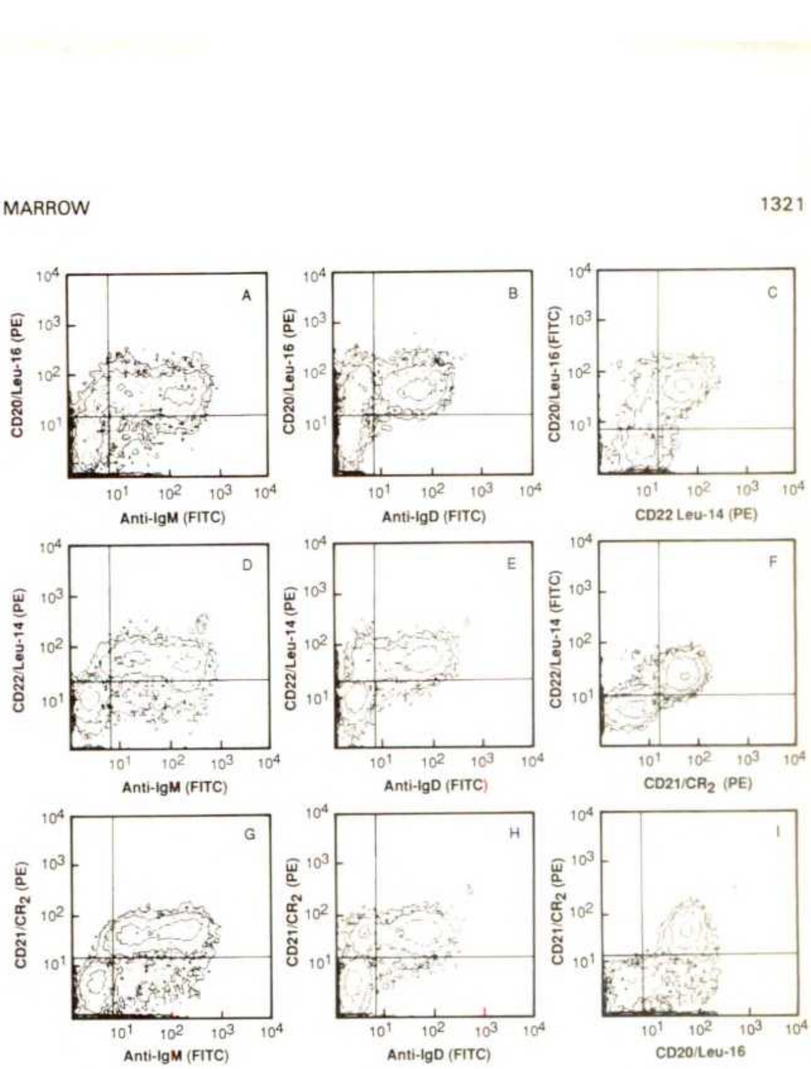

Fig 7. Correlated expression of anti-IgM, anti-IgD, CD20/Leu-16, CD21/CR$_2$, and CD22/Leu-14 on marrow B lineage cells. Only the CD19$^+$ cells (30,000 gated events) were analyzed for the correlation of these five B lymphoid cell surface antigens.

In correlating sIgM with CD22 and CD21 (Fig 7D and G), sIgM was clearly expressed on more marrow B lineage cells than was either CD21 or CD22. When CD22 and CD21 binding was correlated on marrow B lineage cells, the cells identified the same population (Fig 7F). Among the marrow B lineage cells, fewer cells were labeled with sIgD than with either CD20, CD21, or CD22 (Fig 7B, E and H).

DISCUSSION

Adult bone marrow is a complex tissue that is heterogeneous with respect to the multiple lineages represented in a marrow aspirate as well as to maturational differences within each lineage. By identifying cells of the B lineage as distinct from cells of all other lineages, we were able to assess the expression of multiple cell surface markers on cells that differed only in their degree of maturity. The appearance of these cell surface antigens during the maturational process was deduced by comparing in a pairwise fashion the populations labeled by the antibodies.

In these studies, the B lymphoid cells were identified by a combination of light-scattering characteristics (forward and right angle) and the binding of CD19. The light-scattering window used in these studies included essentially all CD19$^+$ cells but excluded cells of both the monocytic and granulocytic lineages.[25] The light-scattering gates were necessary, since the autofluorescence of myeloid cells interfered with the discrimination of the minor subpopulations identified by immunofluorescence.[32] Two-color immunofluorescence showed that CD19 did not label either mature or immature cells of the myeloid lineages. The CD19$^-$ cells classified in this light-scattering window could all be identified as either T, NK, or erythroid cells.[25] In addition, all cells that bound CD19 were identifiable as lymphocytes by morphology. These data are consistent with the studies of non-T ALL in which CD19 was identified as the most precise available antigenic marker of the B lineage.[2]

Three-color immunofluorescence was used to identify the cell surface expression of antigens on the B lymphoid cells in marrow; one color identified the CD19$^+$ B lymphoid cells, and the other two colors compared pairwise the reactivity of additional antigens. The CD19$^+$ population was split into two, almost non-overlapping fractions by the combination of CD10 and CD20. The more mature B lineage cells were identified by the CD20 antigen, whereas the immature B lymphoid cells were CD10$^+$. The CD19$^+$ cells were essentially all double labeled by either CD10 or CD20, suggesting that all the B lymphoid cells were identified in these two populations.

The immature CD10$^+$ B lymphoid cells could be further subdivided by using CD34. An average of 0.6% of marrow cells coexpressed CD19, CD10, and CD34. As found by Ryan and co-workers using lymphocyte-enriched fractions from normal marrow, CD10$^+$ expression was brighter on the CD34$^+$ cells as compared with the remaining CD10$^+$ lymphocytes.[5] Most cells within this population were positive for nuclear TdT.

Class II antigens were not uniformly expressed on marrow B lymphoid cells. HLA-DR was found on all CD19$^+$ cells in marrow but was significantly dimmer on the bright CD10$^+$, CD34$^+$ cells as compared with the more mature CD20$^+$ cells. HLA-DP was not expressed on the brightest CD10$^+$ cells but was found on all other B lymphoid cells. In contrast, HLA-

DQ was found only on the CD20$^+$ cells and not on the less mature CD10$^+$ cells.

The B lymphoid antigens expressed at later stages of maturation reacted only with the CD20$^+$ cells in marrow. Cell surface IgM and HLA-DQ identified the same populations as CD20. In contrast, CD20 reacted with more B lymphoid cells than did CD21, CD22, and anti-sIgD, suggesting that CD20 is expressed before these other antigens.[18]

The data identifying the antigens expressed on B lineage cells can be used to develop a model for the sequential acquisition of cell surface antigens during B lymphocyte development (Fig 8). Our data indicate that the sequence of display of cell surface antigens is highly controlled during development of B cells, with coordinated expression of multiple cell surface antigens at distinct stages during the maturational process. These stages (I, II, III, and IV) are each identified by three or more essentially simultaneous changes in cell surface phenotype.

The most immature cells identifiable in bone marrow express CD34 as well as HLA-DR.[32] CD34 antigen is found on all assayed progenitor cells including CFU-"blast," pre-CFU-GEMM, CFU-GEMM, CFU-GM, CFU-MIX, BFU-E, and CFU-E.[14,33] In the current studies and those of Ryan et al, CD34 is found on the earliest recognizable B lineage cells (CD19$^+$, bright CD10$^+$).[5] This evidence links the CD34 progenitor cell antigen to the B lymphocyte lineage, as well as to the myeloid lineages. HLA-DR was found on these earliest B cells, another characteristic shared by erythroid and myeloid progenitor cells.[32] At this early CD19$^+$, CD34$^+$, HLA-DR$^+$ B cell stage, nuclear TdT and cell surface CD10 are intensely expressed. Because of the presence of TdT in this CD19$^+$, CD34$^+$, bright CD10$^+$ fraction of cells, we speculate that the rearrangement of Ig genes occurs at this stage.[34]

At the beginning of stage II, maturing B lineage cells lose cell surface CD34 and nuclear TdT. At this time, the density of HLA-DR increases fourfold, while the amount of CD10 decreases by a factor of 3. These changes occur with no detectable change in cell size (as assessed by forward light scattering). HLA-DP is detected on cells at approximately this same time.

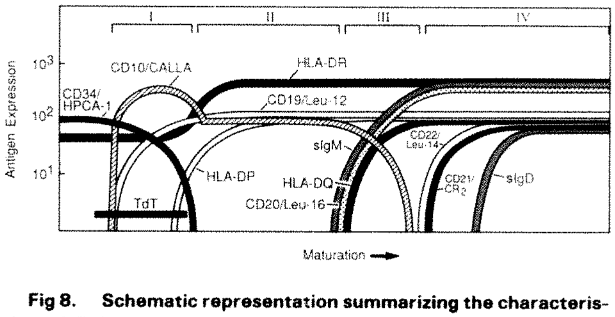

Fig 8. Schematic representation summarizing the characteristics of B lineage cells as they mature in normal human bone marrow. Relative quantities of the cell surface antigens are shown on the abscissa; relative maturation of the cells increases is shown along the ordinate. Four stages of development (I through IV) can be assigned based on multiple changes in cell surface antigen expression that occur at essentially the same time during the maturational process.

The beginning of stage III is marked by the acquisition of CD20, HLA-DQ, and sIgM. The intensity of staining of cells for sIgM, CD20, and HLA-DR is brighter than for HLA-DP, HLA-DQ, or CD19.

The acquisition of two more cell surface markers, CD21 and CD22, and the loss of CD10 identify stage IV. These newly acquired cell surface antigens are not brightly labeled, being expressed in similar amounts as CD19 or HLA-DP. Studies of B lymphoid antigens on peripheral blood indicate that sIgD is expressed on significantly fewer cells than any of the other antigens examined (M.R. Loken and V.O. Shah, unpublished observations). This may explain the data observed in Fig 7B, E, and H and is consistent with stage IV representing peripheral blood contamination of the bone marrow sample. The sIgD$^-$ cells are depicted as more immature cells (as compared with the sIgD$^+$ cells) in Fig 8 to correspond to studies on fetal tissue.[35] Because sIgD is lost after antigenic stimulation, however, the sIgD$^-$ cells observed in blood and marrow may represent the cells that have already been exposed to antigenic stimulation.[36]

The scheme presented in Fig 8 assumes a linear sequence of events in the development of B lymphocytes. The mature B lymphocyte population, as identified in peripheral blood, is assumed to be homogeneous. The lack of expression of sIgD on all peripheral blood B lymphocytes indicates that this assumption is not entirely valid. Other studies must be completed to define where different sublineages of B lymphocytes may deviate from the linear model.

The developmental scheme in Fig 8 is inferred from coordinated expression of cell surface antigens on single samples. Confirmation of the progression from one stage to the next requires the isolation of a particular stage with subsequent induction to the next stage in vitro.

There are differences between the stages of B lymphocyte development identified in this study and those deduced from studies of non-T cell ALL by Nadler and co-workers.[2,3] The most notable difference is in the conclusion from the leukemia studies that CD19 precedes the acquisition of CD10. Nadler et al identified a small group of ALL cases expressing CD19$^+$ and HLA-DR$^+$ but lacking CD10$^-$. In contrast, in our studies on normal B cells, detailed analysis of the CD34$^+$ cells for CD10 and CD19 expression indicated that these antigens were expressed at essentially the same time.[2,3] Similar conclusions were drawn from the studies of Ryan et al.[5] Whether the leukemic cells classified in this group lost the CD10 antigen during the development of the leukemia or if the normal counterpart of this cell is so infrequent (<2% of marrow B cells) that it was not detectable in our studies is not known.

A second difference between our model and that of Nadler et al is that the frequencies of non-T cell ("B lineage") ALL cases classified in the four stages do not appear to reflect the relative proportions of similar populations observed in normal marrow.[3] Almost one-half of the B lineage leukemias had the CD19$^+$, CD10$^+$, CD20$^+$ phenotype, whereas this phenotype constitutes a minor group of normal cells. Although this may be the result of relatively small numbers of patients studied, it is also possible that the leukemic event does not occur randomly during the developmental process and that the proportion of leukemias classified into each group does not reflect the proportion of the normal counterpart in the bone marrow. A third explanation may come from disregulation of expression of different cell surface antigens in the leukemic cells. During the process of leukemogenesis, mutational or other events may occur in which some antigens are deleted or others are incorrectly expressed.[37,38] Such changes would splay the extrapolation from leukemic cells to normal counterparts.

The data presented in this article illustrate that multiparameter flow cytometry can be used to identify a single lineage of cells as distinct from all others in a heterogeneous mixture. By comparing the antigens expressed on only these cells, the composition of that defined population can be assessed. These techniques can be extended to examine the sequential acquisition of antigens in other lineages. In addition, the multiparameter approach can be used to identify populations of cells with abnormal cell surface and physical characteristics that may be indicative of particular disease states or hematopoietic abnormalities.

Therapy of Severe Aplastic Anemia in Young Adults and Children With Allogeneic Bone Marrow Transplantation

By P.B. McGlave, R. Haake, W. Miller, T. Kim, J. Kersey, and N.K.C. Ramsay

During an 8-year period, 28 young adults (median age 27 years) and 30 children (median age 10 years) with severe aplastic anemia have received allogeneic bone marrow transplantation (BMT) from major histocompatibility loci-matched sibling donors after preparation with cyclophosphamide and total lymphoid irradiation (TLI). All recipients were previously transfused. Comparison of post-bone marrow transplantation events in adults and children reveals equivalent median time to engraftment, median duration of hospitalization, median Karnofsky assessment of activity, and equivalent low rejection rate. Although the incidence of moderate and severe acute graft-*v*-host disease (GVHD) and of extensive chronic GVHD was greater in adults than in children, the projected survival at 4 years of adults (67%; 95% confidence interval [CI] 49% to 85%) and of children (73%; 95% CI 57% to 89%) was equivalent. All survivors are transfusion-free and have normal peripheral blood counts. One of 28 adults and 2 of 30 children have experienced rejection, and 1 of these patients survives after a second transplant. No malignancies have been identified following transplantation. An unexpectedly high incidence of hypothyroidism has been detected and may be attributable to preparation of recipients with TLI. Therapy of severe aplastic anemia with allogeneic BMT after preparation with cyclophosphamide and TLI offers a high rate of transfusion-free survival and a low rejection rate in previously transfused young adults and children.

TRANSPLANTATION of bone marrow from HLA-identical siblings has been used successfully to treat severe aplastic anemia. Rejection rates of <10% are common in untransfused recipients.[1,2] Early reports suggested that blood transfusion prior to transplantation resulted in a significant incidence of graft failure and an adverse effect on long-term survival.[3,4] Modifications of the preparative regimens have decreased the rejection rate in this transfused population.[5-8] Improvements in transfusion practices may also have contributed to the reduction in incidence of rejection.[9]

Total lymphoid irradiation (TLI) is a potent form of immunosuppression both in animal models[10,11] and in humans.[12] We have used the combination of TLI and high-dose cyclophosphamide to prepare previously transfused aplastic anemia patients for allogeneic BMT since 1977.[13] In this report, we update our experience with this approach and compare results in children and in young adults.

PATIENTS AND METHODS

Since November 1977, 28 young adults (median age 27 years, range 18 to 45 years) and 30 children (median age 10 years, range 2 to 17.6 years) received BMT as therapy for severe aplastic anemia. Pretransplant recipient and donor characteristics are presented in Table 1. All patients met established criteria for the diagnosis of severe aplastic anemia.[14] All patients were transfused, and all but one had received more than five transfusions, ie, had been exposed to products from more than five separate blood donors prior to BMT. In addition to significant differences in donor and recipient age, adults and children differed in previous transfusion history (<20 *v* >20 transfusions) and in marrow cell dose. All patients or their legal guardians signed informed consent approved by the Committee on the Use of Human Subjects in Research at the University of Minnesota.

Patients were prepared for transplantation with a regimen designed to minimize rejection[12] including cyclophosphamide, 50 mg/kg/day intravenously (IV) (day −6 to day −3), and TLI, 750 cGy midline dose at the umbilicus (day −1). TLI was given in a single dose at a rate of 26 cGy/min with a 4-MV linear accelerator. Patients then received marrow from major histocompatibility (MHC)-matched sibling donors (day 0). All patients received graft-*v*-host disease (GVHD) prophylaxis with methotrexate.[15] Twenty-nine patients received additional GVHD prophylaxis with equine antithymocyte globulin (ATG) and prednisone.[16] Four patients received 5 mg/day of OKT3 given IV from day +8 to day +20 in addition to methotrexate and prednisone.[17]

Acute GVHD organ involvement was graded I through IV.[15] Chronic GVHD was scored as limited or extensive.[18] The term "advanced GVHD" was applied to patients who developed either grade II or greater acute GVHD or extensive chronic GVHD. Mild cutaneous acute GVHD and limited chronic GVHD were treated with topical steroid cream. Advanced GVHD was treated with regimens containing systemic steroids and, in some cases, adjunctive ATG, cyclosporine, or azathioprine therapy.

Statistical methods. Clinical and laboratory data were retrieved from the University of Minnesota Bone Marrow Transplant Database, which contains systematically and prospectively collected data for all BMT recipients and donors. Univariate analyses were performed using the Kaplan-Meier product-limit method to assess the effects of various factors on survival.[19] The Mantel-Cox statistic was used to compare the difference in survival between groups. The sole exception involved assessment of the possible influence of GVHD on survival. Because GVHD is not a baseline patient characteristic and occurs some time after transplant, it was treated as a time-dependent covariate in a Cox proportional-hazards regression analysis.[20] Factors that were significantly associated with survival in univariate analysis were then entered into a Cox stepwise multivariate regression analysis to determine their independent contributions to survival.

RESULTS

Projected survival at 4 years for the adult group is 67% (95% CI 49% to 85%), whereas that of the children is 73%

†Six adults and five children died before day 100 and are censored at time of death.

(95% CI 57% to 89%) ($P = .58$) (Fig 1). The latest death in the series occurred at 11 months following BMT. All survivors are transfusion independent. Characteristics of post-BMT of the two groups (Table 2) including median times to engraftment, median durations of hospitalization, median Karnofsky assessments of activity in survivors, and rejection rates are equivalent.

GVHD. The incidence and severity of GVHD in adults and in children is shown in Table 2. Kaplan-Meier analysis revealed a higher incidence of moderate and severe acute GVHD at 100 days in adults (54%; 95% CI 35% to 73%) than in children (24%; 95% CI 9% to 40%) ($P = .08$), and a significantly higher long-term projected incidence of extensive chronic GVHD in adults (56%; 95% CI 35% to 78%) than in children (12%; 95% CI = 0% to 25%) ($P = .008$). The long-term projected incidence of advanced GVHD in adults of 68% (95%; CI 49% to 86%) was significantly greater than the 36% projected incidence (95%; CI 18% to 54%) seen in children ($P = .02$) (Fig 2). Twelve patients in this series have required systemic steroid therapy and, in some cases, adjunctive therapy with azathioprine for extensive chronic GVHD. Three of these 12 patients have died, whereas 8 patients have experienced complete resolution of chronic GVHD and are no longer receiving immunosuppressive therapy. One patient is receiving low doses of azathioprine as therapy for persistent cutaneous chronic GVHD.

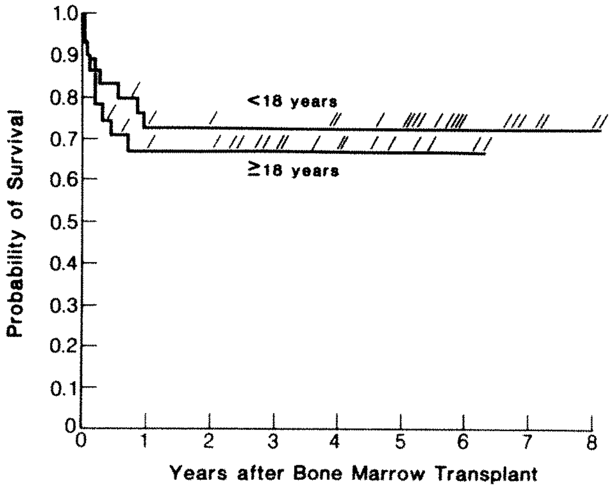

Fig 1. Projected long-term survival of 30 children (<18 years) and 28 adults (18 to 44 years) undergoing BMT for SAA. One surviving child who experienced marrow failure and was retransplanted is a transfusion-free survivor at +78 months.

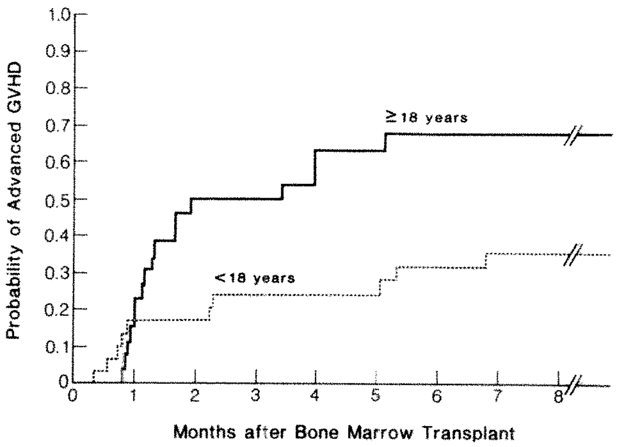

Fig 2. Projected incidence of advanced GVHD in 28 adults and 30 children undergoing allogeneic BMT for SAA. The term "advanced GVHD" defines patients who developed either moderate or severe acute GVHD or extensive chronic GVHD. Last event on either curve is at 22 months. Dead patients have been censored.

Graft failure. Three of 58 patients experienced nonengraftment or rejection following BMT. A 9-year-old girl (UPN 96) with idiopathic severe aplastic anemia who had received <20 transfusions prior to transplantation failed to engraft following an infusion of 3.9×10^8 nucleated bone marrow cells/kg of recipient weight from her MHC-matched brother. A second infusion of 4.4×10^8 cells per cells per kilogram of recipient weight from the same donor following preparation with cyclophosphamide, procarbazine, and ATG was unsuccessful, as was a third infusion of 1.7×10^8 cells/kg of recipient weight. The patient died at +99 days with *Escherichia coli* sepsis and *Aspergillus sp* pneumonia. No evidence of engraftment could be found at time of death.

A 7-year-old girl (UPN 103) with idiopathic severe aplastic anemia who had received <20 transfusions prior to transplantation had successful engraftment at day +25 after receiving 3.9×10^8 cells/kg of recipient weight from her MHC-matched sister. Twenty-nine months later, the patient returned with recurrent severe aplastic anemia. After preparation with cyclophosphamide, 50 mg/kg/day (day −5 to day −2) and TBI 300 cGy (day −1), the patient received 3×10^8 bone marrow cells/kg of recipient weight from the same donor and engrafted at day +19. She is now alive and well at +45 months following a second BMT.

A 26-year-old man (UPN 410) with idiopathic severe aplastic anemia who had received >20 transfusions prior to BMT as well as an unsuccessful course of equine ATG (Minnesota) failed to establish a graft following preparation with cyclophosphamide and TLI, and an infusion of 3.2×10^8 cells/kg of recipient weight donated by his MHC-matched brother. Peripheral blood evidence of engraftment occurred on day +19 and was confirmed by bone marrow biopsy. Aplasia recurred at day +45 and was treated by infusion of 3.1×10^8 cells/kg of recipient weight using bone marrow cells from the same donor following preparation with cyclophosphamide, cytosine arabinoside, and TBI. Engraftment did not occur, and the patient died at day +120 with *Aspergillus sp* pneumonia.

Thyroid dysfunction. "Compensated hypothyroidism," defined as elevation of serum thyroid stimulating hormone (TSH) serum levels >10 μIU/ml on at least one occasion or between 7 to 9.9 μIU/ml on at least two occasions in the presence of a normal T4 index, occurred in 13 of 37 recipients studied at >2 years after BMT. "Primary hypothyroidism," defined as concomitant depression of the serum T4 index (<5) and the above-defined serum TSH elevation, occurred in an additional three recipients.

Pneumonia. In this series, pneumonia occurred in 31 of 58 patients. Etiologies included cytomegalovirus (CMV) (5 cases), fungus (3 cases), bacterial infection (3 cases), *Pneumocystis carinii* (3 cases), acute respiratory distress syndrome (ARDS) (1 case), and pulmonary hemorrhage (1 case). In 15 cases, no etiology was determined.

Cause of death. Seventeen of the 58 patients studied have died. Primary causes of death are listed in Table 3. In 9 of the 17 cases, pneumonia was considered the principal clinical event responsible for death. In one case (UPN 129) rapid onset of fatal pulmonary edema occurred in a patient receiving concomitant amphotericin B empiric therapy and WBC infusion. In a second case (UPN 525), death was related to uncontrollable hemorrhage into the lung after ear, nose, and throat (ENT) surgery. In the remaining 7 cases fatal pneumonia could be attributed to CMV (5 cases), *Candida sp* (1 case), or a bacterial pathogen (1 case). In 4 cases, sepsis with either bacterial pathogens (3 cases) or with CMV (1 case) accounted for death. Meningitis from *Staphylococcus sp* and from *E coli*, respectively, occurring in patients with advanced GVHD, accounted for two additional deaths related to infection. Finally, two patients previously described (UPN 96, UPN 410) died of infectious complications associated with graft failure and prolonged pancytopenia. Advanced GVHD was considered a contributing feature in 11 of the 17 deaths.

Table 3. Cause of Death

Total	11	17

*Single clinical feature considered most important in patient death.

†GVHD or GVHD therapy considered a contributing factor in patient death.

Survival. Univariate Kaplan-Meier analyses were performed to assess the influence of patient characteristics on survival. No significant correlation with survival could be found when recipient age or sex, donor age or sex, recipient/donor sex match, or GVHD prophylaxis were considered. Prolonged interval from diagnosis to BMT defined as greater than the median interval of 46 days ($P = .01$) and an extensive pretransplant transfusion history (>20 U) ($P = .02$) predicted decreased survival. The occurrence of advanced GVHD was treated as a time-dependent covariate in a Cox regression analysis of survival. Those with advanced GVHD had significantly decreased survival ($P = .0004$). Survival was also analyzed by decade of recipient age (Table 4). Although patients aged >30 years had a trend toward poorer survival, there was no significant difference in survival among the four age groups ($P = .75$).

A Cox multivariate analysis was then conducted to assess the independent contribution of factors that were significant

Table 4. Projected Long-term Survival by Decade

Age	Number	Survival (%)	95% CI
0-9	16	75	54-96
10-19	20	75	55-94
20-29	12	67	40-93
30-44	10	58	27-90

Table 4 depicts the projected long-term survival of BMT recipients analyzed by age. There is no significant difference in projected survival among the four groups ($P = .75$)

in univariate analyses. Because the effect of recipient age on outcome was of interest, it was included in the analysis and was forced into the model at the first step. The results of this analysis are presented in Table 5. Advanced GVHD (P = .002) and a prolonged interval from diagnosis to transplant (P = .01) predicted poorer outcome. Neither recipient age nor previous transfusion history significantly influenced survival when occurrence of advanced GVHD and interval from diagnosis to BMT were taken into account.

DISCUSSION

In this report, we demonstrate that transplantation of bone marrow taken from MHC-matched sibling donors provides excellent survival for previously transfused children and young adults with severe aplastic anemia. Preparation of recipients with high-dose cyclophosphamide and TLI is associated with a low rejection rate (3 of 58) in a group considered at high risk for marrow failure and has not been associated with occurrence of malignancy. Prolonged interval from diagnosis to transplantation and development of advanced GVHD independently predict poor outcome. The flat, transfusion-free survival curve from 11 months to 9 years (Fig 1) reflects the virtual absence of life-threatening complications occurring in patients surviving the acute posttransplant course.

A graft failure rate of <10% has been consistently reported when untransfused patients receive BMT therapy for severe aplastic anemia.[1,2] Early reports suggested that transplantation of previously transfused patients resulted in a significant incidence of graft failure and an adverse effect on long-term survival.[3,4] Graft failure was attributed to nonspecific sensitization of the recipient by antigens found in transfused blood products.[21,22]

Subsequently, modifications of the preparative regimen have been designed to reduce the rate of graft failure in transfused recipients. Addition of nonirradiated donor peripheral blood buffy coat following marrow infusion has reduced the incidence of graft failure from 32% to 14%.[5] Infusion of buffy coat, however, is associated with an increased incidence of chronic GVHD.[23]

Immunosuppression with a combination of total body irradiation (300 cGy) given in a single dose and high-dose cyclophosphamide resulted in a projected survival rate of 61% and rejection in only 1 of 44 previously transfused severe aplastic anemia patients. A high incidence of interstitial pneumonitis and a high mortality in adults, however, was reported.[6] Addition of cyclosporine to the BMT preparative regimen has been reported to reduce the risk of early graft failure.[7] A subsequent report from the same authors, however, demonstrated that unexpected late graft failures may occur after withdrawal of cyclosporine therapy.[24] When immunosuppression with cyclosporine is combined with high-dose cyclophosphamide, both early graft failure and fatal venoocclusive disease of the liver can occur.[25] Preparative immunosuppression with a combination of procarbazine, rabbit antithymocyte serum (ATS), and high-dose cyclophosphamide has also been reported to provide a low rejection rate (10%) and acceptable projected long-term survival (61%) in a group of relatively young recipients (median age 17 years).[8]

Table 5. Multivariate Analysis of Characteristics Predicting Poor Outcome

Characteristic	Relative Risk	Significance (p Value)
Advanced GVHD	5.9	.002
Prolonged interval from diagnosis to BMT	2.4	.01
History of >20 transfusions prior to BMT	—	.10
Age >18 years	—	.58

Table 5 depicts results of stepwise multivariate analysis correlating various risk features with death in 58 transfused patients undergoing BMT for SAA.

The 5% rejection rate in this series compares favorably with rejection rates reported after BMT therapy of either untransfused or previously transfused aplastic anemia patients. This low rejection rate is probably the result of preparative immunosuppression with TLI, which was first shown to be immunosuppressive in animal models.[10,11] Other researchers have reported preliminary results suggesting a low rejection rate after preparation of transfused aplastic patients with low-dose TLI.[26] Radiation ports used to deliver TLI include portions of the thyroid gland. In this series, 16 of 37 recipients studied at >2 years following transplantation had chemical evidence of hypothyroidism.[27,28] Endocrine abnormalities occurring after preparation with single-dose TBI and allogeneic BMT have been reported.[29] Hypothyroidism occurring after mantle irradiation therapy of Hodgkin's disease is also common, often clinically insignificant, and sometimes reversible without therapy.[30,31] TLI may have similar adverse effects when used for bone marrow transplantation therapy of severe aplastic anemia.

Pneumonia was a principal clinical feature in 9 of the 17 deaths in this series. The contribution of irradiation to the development of fatal pneumonia is difficult to determine. Damage to the pulmonary bed itself is unlikely since individually tailored lung shielding permitted <10% of the total calculated dose of irradiation to penetrate the center of the lung block in all recipients. In seven of the nine cases of fatal pneumonia, an infectious pathogen was demonstrated. The additive immunosuppressive effect of TLI and cyclophosphamide may have predisposed recipients to pneumonia in these cases. Most recipients with fatal pneumonia, however, also were receiving treatment for advanced GVHD. GVHD and therapy for GVHD have been associated with the development of pneumonia following allogeneic BMT for leukemia.[32] The relative importance of these etiologic features on the development of fatal infectious pneumonia is not known.

The long-term, projected incidence of advanced GVHD was 67% in adults and 36% in children, and advanced GVHD contributed significantly to mortality in this series. The reason for the disparity between the projected incidence of GVHD in adults and in children is not obvious. An increased incidence of GVHD has occurred in severe aplastic anemia patients receiving nonirradiated donor buffy coat infusions.[23] Adults in this series, however, received a lower median cell dose per kilogram of recipient weight (3.2×10^8) than did children (3.8×10^8) (P = .05), and neither children nor adults received donor buffy coat infusions. The relative importance of older donor age in the development of GVHD is difficult to assess in this series since donor age parallels recipient age in both the older and in the younger group. Despite the increased incidence of advanced GVHD in adults, no significant disparity in parameters associated with outcome (including time to engraftment, rejection rate, median length of hospitalization, or median Karnofsky assessment of survivors) could be found. Recent reports suggest that prophylaxis with the combination of methotrexate and cyclosporine after allogeneic BMT therapy for severe aplastic anemia can result in an extremely low cumulative incidence of moderate or severe acute GVHD (14%) with a low rejection rate and with excellent projected survival.[33] Studies that compare the relative merits of our current acute GVHD prophylaxis to prophylaxis with the combination of methotrexate, cyclosporine, and prednisone are underway at our institution.

In this study, excellent long-term transfusion free survival occurred in both young adults (18 to 44 years) and in children (1 to 17 years). Comparison of survival by decade demonstrated no significant difference, although only 10 adult recipients were between the ages of 30 and 44 years. An inverse correlation of survival and increasing recipient age following BMT for severe aplastic anemia has been reported[6]; however, the comparable survival in children and young adults in our series is in agreement with two recently reported analyses.[34,35]

The observation has been made that patients receiving allogeneic BMT therapy for severe aplastic anemia in the "modern era" have lower rejection rates and better survival than patients transplanted with similar preparative regimens in earlier years. Low rejection rates, comparable to those that are observed after transplant of untransfused severe aplastic anemia patients, have been attributed to a decreased incidence of recipient sensitization accompanying improvements in blood product transfusion procedures.[9] Better overall survival may be attributable to expedited therapy with BMT, and better pretransplant and posttransplant support.[8] The results of our study are in agreement with reports of better survival in recently transplanted patients. In our experience, projected long-term transfusion-free survival of 28 patients (median age 14 years) transplanted from 1977 to 1981 is 61% (95% CI 43% to 79%), whereas projected long-term survival of 30 patients transplanted from 1982 to 1986 (median age 21 years) is 79% (95% CI 64% to 94%) ($P = .10$).

Allogeneic bone marrow transplantation therapy for severe aplastic anemia after preparation with a combination of cyclophosphamide and TLI provides excellent transfusion-free survival and an extremely low rate of graft failure in young adults and in children. Results of this approach compare favorably with those that have been observed after transplantation with other reported preparative regimens or after therapy with alternative forms of immunosuppression.

Mixed Hematopoietic Chimerism Following Bone Marrow Transplantation for Hematologic Malignancies

By Lawrence D. Petz, Priscilla Yam, R. Bruce Wallace, A. Dean Stock, Gerda de Lange, Robert G. Knowlton,
Valerie A. Brown, Helen Donis-Keller, L. Robert Hill, Stephen J. Forman, and Karl G. Blume

Twenty-nine of 172 patients (17%) who received an allogeneic bone marrow transplant (BMT) from histocompatible sibling donors for hematologic malignancies were mixed hematopoietic chimeras; ie, they had a mixture of donor and host hematopoietic or lymphohematopoietic cells at ≥14 days after transplantation. Twenty-four of the 29 mixed chimeras (83%) have remained in continuous complete remission for up to 116 months (>9 years) following BMT. Four of the 29 patients (14%) have had recurrent leukemia, and 7 of the 29 (24%) have had moderate or severe graft-*v*-host disease (GVHD). Twelve of these 29 patients have persisted as stable mixed chimeras for ≥2 years after BMT, whereas other patients converted to all donor-type hematopoiesis. The incidence of mixed chimerism was independent of the pretransplant regimen, the donor or recipient age (<20 *v* >20 years), remission status (first complete remission of acute leukemia and first chronic phase of chronic myelocytic leukemia *v* later stages of disease), and type of leukemia. Our data indicate that mixed hematopoietic chimerism is not rare after BMT for hematologic malignancies and that its presence is compatible with long-term disease-free survival. Prospective studies of mixed chimerism after BMT are warranted to achieve better understanding of its biologic importance.

© *1987 by Grune & Stratton, Inc.*

WE PREVIOUSLY reported nine patients treated with high-dose radiochemotherapy and allogeneic bone marrow transplantation (BMT) for acute leukemia who became mixed hematopoietic chimeras; that is, they had blood cells of both donor and recipient origin.[1,2] We have subsequently carried out studies on 172 patients treated with radiochemotherapy and BMT for hematologic malignancies to characterize mixed chimerism in detail, to document its incidence using two different preparatory regimens, and to determine its relationship to graft-*v*-host disease (GVHD), leukemic relapse, and disease-free survival. We also evaluated the advantages and disadvantages of several genetic markers for such studies, including the use of DNA restriction fragment length polymorphisms (RFLPs).[3]

PATIENTS AND METHODS

Patient Population

We evaluated 293 patients who received an allogeneic bone marrow transplant for leukemia at the City of Hope National Medical Center between May 18, 1976 and December 31, 1985. Patients with a unique patient number (UPN) of 1 to 281 were evaluated retrospectively, whereas patients with a UPN of 282 to 336 were studied prospectively. We considered only patients who had one or more informative genetic markers tested after BMT to determine the presence or absence of host-type hematopoietic cells. Detailed information is available in 172 patients at this time. The diagnoses were as follows: acute lymphocytic leukemia (ALL), n = 65; acute nonlymphocytic leukemia (ANLL), n = 72; chronic myelocytic leukemia (CML), n = 32; refractory anemia with excess blasts, n = 1; chronic myelomonocytic leukemia (CMMOL), n = 1; and hairy cell leukemia, n = 1. All patients received a marrow transplant from histocompatible sibling donors.

Preparatory Regimens

Patients with a UPN of 1 to 185 were treated with a pretransplant preparative regimen (regimen 1) consisting of cytosine arabinoside (Ara-C), high-dose cyclophosphamide, and 1,000 cGy total body irradiation (TBI) delivered at 7 cGy/min,[4] except for patients 78 and 100 who received 750 cGy of TBI at a dose rate of 26 cGy/min. The preparative regimen for patients 186 to 334 (regimen 2) consisted of 1,320 cGy TBI given in 11 fractions of 120 cGy,[5] and cyclophosphamide, VM 26, or VP 16.[6]

The posttransplant immunosuppressive regimen for patients 1 to 177 consisted of methotrexate and prednisone,[4] whereas subsequent patients were randomized to receive either methotrexate and prednisone or cyclosporine and prednisone.[7]

Genetic Markers

The following genetic markers were used: RBC antigens, sex chromosomes, immunoglobulin allotypes, and DNA restriction fragment length polymorphisms (RFLPs).

RBC antigens and antibodies. RBC phenotyping was performed using standard techniques.[8] Typing for the following antigens was performed: A_1, B, A, D, C, E, c, e, K, k, Fy^a, Fy^b, Jk^a, Jk^b, P_1, M, N, S, and s. Transfusions prior to referral for transplantation occasionally made the determination of the patient's RBC phenotype difficult. In those instances, reticulocyte enrichment of the patient's RBCs[9] aided in establishing the correct phenotype. It was frequently also impossible to exclude mixed chimerism by RBC antigen typing during the first 3 to 5 months after transplantation because of transfusions. In ten patients, the presence of donor-type RBC antigens after BMT in the absence of mixed field reactions was

considered an indication of complete allogeneic marrow engraftment.

We interpreted an RBC alloantibody or an autoantibody in a patient prior to BMT that remained detectable for >6 months after BMT as an indication of the persistence of host B lymphocytes. This occurred most commonly in transplants involving a major ABO blood group incompatibility (eg, donor group A, patient group O), which was present in 11 patients (UPN 38, 47, 78, 95, 108, 118, 168, 233, 268, 279, and 320). We selected the 6-month period as being well beyond the expected duration of persistence of antibody since previous studies have indicated that patients' RBC alloantibodies ordinarily persist for no longer than 120 days after BMT.[10]

Cytogenetic studies. In patients who received marrow from a donor of the opposite sex, cytogenetic analyses were performed,[11] usually using bone marrow specimens. In some instances, peripheral blood lymphocytes were used instead, in which case the lymphocytes were cultured in a conditioned medium described by Mills et al.[12] This medium activates a wide variety of T and B cells as indicated by studies of T and B cell neoplasms in our laboratory (A.D. Stock et al, unpublished observations). The presence of the Y chromosome was detected by screening metaphases after quinicrine staining or using C-banding. When adequate numbers of metaphases were available, at least 30 were so screened.

Immunoglobulin allotyping. Immunoglobulin allotyping was performed using hemagglutination inhibition. The method and the reagents used were as previously reported.[13,14] To exclude the presence of exogenous immunoglobulins as a result of blood transfusion, allotyping was performed at ≥100 days after the most recent transfusion.

DNA RFLP analysis. Restriction fragment analysis was performed as previously described.[3] In brief, high-mol-wt DNA was isolated from the nuclei of peripheral blood cells obtained from ~25 mL blood collected in heparin or in 10% acid-citrate-dextrose. The purified DNA was digested with restriction endonucleases; the DNA fragments were then fractionated by electrophoresis in 0.5% to 1.0% agarose gels, and hybridization was carried out using the appropriate probes either in gel or after Southern blotting[15] using nitrocellulose (Schleicher and Schuell, Keene, NH), Genetran (Plasco, Woburn, MA), or Zeta-bind (AMF Cuno, Meriden, CT) filters.

A panel of ten DNA probes was available for hybridization.[3] These included pAW101[16] (obtained from Dr Ray White, Salt Lake City), pDP34[17-19] (obtained from Dr David C. Page, Boston), AT3[20] (obtained from Dr David Ginsburg, Ann Arbor, MI), Gγ and Aγ globin gene oligonucleotide probes (prepared by one of us, RBW), and five randomly cloned single copy DNA sequences termed LAM4-123, -1065, -427, -355, and -1214[21] prepared and characterized at Collaborative Research, Inc (Lexington, MA). The genomic probes were labeled by nick translation with ^{32}P-deoxynucleotide triphosphate (New England Nuclear, Boston) to a specific activity of 1 to 10 × 10^8 CPM/μg DNA; 5' end labeling of oligonucleotide probes was performed using T4 polynucleotide kinase.[22]

Definitions

We defined a patient as a "complete chimera" when genetic markers detected only donor-type hematopoietic cells after BMT.[23] We defined a transplant recipient as a "mixed hematopoietic chimera" or "mixed chimera" if the patient had a mixture of donor and host hematopoietic or lymphohematopoietic cells ≥14 days after BMT. We have excluded those patients who were complete chimeras and subsequently had a reemergence of host cells only at or near the time of relapse of their leukemia. In this regard, we excluded ten patients who developed hematologic evidence of relapse within 90 days of the reemergence of detectable host cells.

RESULTS

Incidence of Mixed Hematopoietic Chimerism

One of the aims of our study was to determine the incidence of mixed hematopoietic chimeras following BMT and, in particular, to determine if there was a difference in incidence in patients treated with 1,000 cGy single-dose TBI (regimen 1) as compared with patients treated with 1,320 cGy fractionated TBI (regimen 2). Twenty-nine of the 172 patients studied (17%) were mixed hematopoietic chimeras. Eighteen of 81 patients (22%) treated with regimen 1 and 11 of 91 patients (12%) treated with regimen 2 became mixed chimeras. This difference in incidence is not statistically significant (P = .10). The clinical characteristics of the mixed hematopoietic chimeras are presented in Tables 1 and 2. Mixed chimeras have been documented among patients with various types of leukemia; ie, 12 of the patients had ALL, 13 had ANLL, 2 had CML, 1 had chronic myelomonocytic leukemia, and 1 had hairy cell leukemia.

Frequency of Informative Markers and Sensitivity of the Various Genetic Markers

RBC antigen phenotyping prior to BMT in 275 donor/recipient pairs revealed donor and recipient markers in 201 pairs (73%), only recipient-specific markers in 37 pairs (13%), only donor-specific markers in 29 pairs (11%), and no markers in 8 pairs (3%). A minor population of RBCs can generally be detected by RBC phenotyping when their percentage is as low as 1% to 5% of the total.

Immunoglobulin allotype testing in 75 donor/recipient pairs revealed a recipient-specific marker or both donor-specific and recipient-specific markers in 37 pairs (49%), donor-specific markers in 12 pairs (16%), and no markers in 26 pairs (35%). Immunoglobulin allotypes can be detected to a level of ~3% of normal.

DNA RFLP can be informative in essentially 100% of donor/recipient pairs depending on the number of probes used for hybridization and their polymorphism information content.[3,21,24,25] Using probes pAW101, pDP34, AT3, Gγ globin, and Aγ globin, a recipient-specific marker or both recipient-specific and donor-specific markers were present in 38 of 40 (95%) donor/recipient pairs tested. With the five LAM4 randomly cloned genomic probes,[3,21] the observed frequency of finding a recipient-specific marker in 30 sibling pairs was 100%. DNA RFLP can detect ~5% to 10% of a minor population of donor or host DNA.[3,21,25,26]

The sensitivity of sex chromosome analysis for detection of host cells depends on the number of cells examined. For example, one must examine ≥59 cells to exclude 5% host cells with 95% confidence.[27]

Results of Genetic Marker Studies

The results of the genetic marker studies used to define the patients as being mixed hematopoietic chimeras are shown in Tables 3 and 4. As indicated, some of the patients have remained stable mixed chimeras for extended periods of time (eg, UPN 78, 100, and 144) whereas others eventually

converted to all donor-type hematopoiesis (eg, UPN 233 and 283).

The percentages of host cells in mixed chimeras varied from patient to patient and were most readily determined from chromosome analysis when adequate numbers of metaphases were available. Of the 11 patients determined to be mixed chimeras by chromosome analysis, ≥30 metaphases were examined in 9 patients; in the other 2 patients, 80 and 20 metaphases were examined, respectively. Six of the 11 patients had >50% host cells, and the other 5 patients had 2.5%, 5%, 10%, 15%, and 28% cells of host origin. Repeat studies revealed a similar percentage or a decreasing percentage of host cells. Bone marrow was the source of the specimens in 8 of the 11 patients, peripheral blood was the source in 1, and both marrow and blood were the sources in 2.

The percentage of host cells on initial diagnosis of patients as mixed chimeras did not predict whether the patient would be a stable mixed chimera or would convert to a complete chimera. For example, of those mixed chimeras who converted to all donor-type cells, the initial proportion of host-type cells was only 2% and 10% in patients 38 and 260, respectively, but was 87% and 90% in patients 233 and 234.

The percentages of host and donor erythrocytes were estimated by observance of the mixed field reactions using RBC typing reagents. RBCs were largely of host origin in

Numbers following Mixed refer to months after BMT at which time mixtures of donor and recipient cells were found (mixed chimeras). Numbers following Complete refer to months after BMT at which time only donor genetic markers were detected. Numbers following Host refer to number of months after BMT at which time only cells of host type were found. NA, not applicable (donor and recipient of same sex); NI, not informative.

patients 78, 100, and 108, whereas they were largely of donor origin in patients 95, 101, 118, 152, 160, 163, 179, 222, and 233. Approximately equal percentages of RBCs of donor and host origin were found in patients 64 and 144.

The percentage of host immunoglobulins was determined in selected patients by titration using doubling dilutions of the patients' sera. Approximately 3% to 6% of host immunoglobulins were present in patients 160, 168, 222, and 226. In patients 152, 160, and 222, immunoglobulin allotypes ultimately became the only indication of the presence of host-type cells, whereas earlier in these patients' courses other genetic markers had also indicated mixed chimerism.

Quantitative studies were not performed using DNA RFLPs. Nevertheless, in patients 78, 100, and 144 a comparison of the intensity of the bands of donor and recipient origin made it evident that ≥50% of the DNA was of host origin, in agreement with the results of other genetic markers.

Correlation of Results of Various Genetic Markers

Cytogenetic studies and RBC phenotyping were performed concurrently in a number of patients. Both methods indicated a predominance of host cells in patients 78 and 100, a predominance of donor cells in patient 160, and approximately equal percentages of host and donor cells in patient

144. In patients 101, 152, and 179, RBC phenotyping indicated a small population of host cells, whereas cytogenetic studies revealed only cells of donor origin. In patients 234 and 323, RBCs were all of donor phenotype, whereas a small percentage of host cells (2.5% and 10%) were detected on a single examination in each patient by chromosome analysis. In patient 233, RBCs were largely of donor origin, and host cells were detected by chromosome analysis in one of six studies.

In patient 283, in vitro mixing experiments using mixtures of DNA of host and donor origin indicated that ~20% of DNA was of host origin at a time when 9 of 60 metaphases (15%) were of patient type.

RBC antibodies persisting >6 months after BMT served as the basis of diagnosing mixed chimerism in 7 patients; in 2 of these patients immunoglobulin allotyping also indicated mixed chimerism, whereas in the other 5 patients immunoglobulin allotyping either was uninformative or was not performed. Anti-A or anti-B antibodies were present in 6 patients and caused a direct antiglobulin test without hemolysis in 2 patients, a positive direct antiglobulin test with transient hemolytic anemia in 1 patient, and a delayed onset of erythropoiesis (170 days to >605 days after BMT) in 3 patients.[28,29] As with other genetic markers, host RBC alloantibodies ultimately disappear in most patients, but patient 279 still has a high titer anti-A antibody. She is also transfusion dependent because of a lack of erythropoiesis by the engrafted marrow >605 days after BMT.[29]

Clinical Outcome

In this largely retrospective study, all marrow transplant patients who were seen in follow-up during the study period were included. An analysis of our data revealed, however, that patients who were complete chimeras were first studied at a median of 3 months posttransplant (range 0.5 to 103 months), whereas those patients who were mixed chimeras were first studied at a median of 6 months posttransplant (range 0.75 to 72 months). A statistical comparison of clinical outcome of mixed chimeras and complete chimeras is therefore not feasible. Nevertheless, it is noteworthy that 24 of the 29 mixed chimeras (83%) have remained in continuous complete remission (CCR) and that only 4 of the 29 mixed chimeras (14%) have had a relapse of their hematologic malignancy. In addition, the incidence of moderate and severe GVHD in this heterogeneous population was 24%.

DISCUSSION

Our data indicate that 29 of 172 (17%) patients treated with marrow ablative high-dose radiochemotherapy and BMT for hematologic malignancies became mixed hematopoietic chimeras. Twelve of these 29 patients were mixed chimeras for ≥2 years after BMT, as documented by one or more genetic markers. Moreover, 24 of the 29 mixed chimeras (83%) have remained in CCR for up to 116 months (>9 years) following BMT.

The existence of mixed hematopoietic chimeras who are in long-term CCR indicates that the mechanism by which remission is produced is not simply that of marrow ablation followed by rescue with donor marrow. A graft-*v*-leukemia effect[30,31] may contribute to the maintenance of remission after BMT, but this effect is not essential since long-term CCR can occur after syngeneic marrow transplantation and after chemotherapy alone. Thus, the mechanism by which high-dose radiochemotherapy and BMT lead to mixed chimerism and long-term remission may be the selective destruction of a leukemic clone while allowing for repopulation of the marrow with normal endogenous hematopoietic cells along with growth of donor cells. Alternatively, since evidence exists for a multistep pathogenesis of some leukemias,[32] therapy in some patients may eradicate a leukemic subclone, resulting in restoration of morphologically and cytogenetically normal marrow even though an abnormal clone of host cells may persist.[32] Indeed, the presence of a clonal population of mature blood cells in patients in complete hematologic remission has been reported.[33,34]

Only 4 of 29 mixed chimeras not in overt hematologic relapse within 90 days of the time of detection of host cells subsequently relapsed. On the other hand, we[3] and other authors[35] have pointed out that a progressive increase in the percentage of host cells is associated with a poor prognosis due to recurrent disease. Thus, when mixed chimerism is diagnosed, follow-up genetic marker studies and hematologic tests are necessary to distinguish relapse from stable mixed chimerism.

Factors that lead to the production of mixed chimerism after high-dose radiochemotherapy in some patients but not others have not been identified. In our patients, the incidence of mixed chimerism was independent of the pretransplant regimen, the donor or recipient age (<20 *v* >20 years), remission status (first complete remission of acute leukemia and first chronic phase of chronic myelocytic leukemia *v* later stages of disease), and type of leukemia.

A major ABO blood group incompatibility was present in 11 of 29 (38%) patients who became mixed chimeras but in only 20 of 143 (14%) patients who became complete chimeras. This difference is statistically significant ($P = .006$). If the three patients whose only genetic marker was an RBC alloantibody are excluded however, the difference is no longer significant. Thus, the higher incidence of mixed chimerism in transplants in which there is a major ABO blood group incompatibility may reflect that a test for RBC alloantibodies is a more sensitive marker than the other genetic markers used. Patients without major ABO incompatibilities are not eligible for such an analysis.

Mixed hematopoietic chimerism has also been reported after BMT by other investigators.[23,25,26,32,35,36-43] Indeed, Hill et al[23] reported the remarkable fact that the incidence of mixed chimerism was 58.3% in their series of 96 patients who received a marrow transplant for aplastic anemia. Mixed chimerism persisted for up to 395 days posttransplant, with the graft then being rejected or, more commonly, with hematopoiesis converting to 100% donor-type cells. The Kaplan-Meier estimate of the probability of developing grades II to IV acute GVHD for mixed chimeras and complete chimeras was significantly different, showing an increase in the frequency of acute GVHD in the complete chimeras. The marrow rejection rate, however, was significantly increased in mixed chimeras as compared with complete chimeras although the projected survival rate was not different.

Prospective studies of mixed hematopoietic chimeras after BMT are warranted for a better understanding of its biologic importance. Moreover, insights into basic aspects of transplantation biology may be possible by analysis of hematopoietic repopulation in the posttransplant period.

ACKNOWLEDGMENT

We are indebted to Paige Patch for invaluable secretarial assistance. We thank Afred M. van Leeuwen and Peter H. van Eede for their excellent technical assistance.

Association of a Chromosomal 3;21 Translocation With the Blast Phase of Chronic Myelogenous Leukemia

By Charles M. Rubin, Richard A. Larson, Mitchell A. Bitter, John J. Carrino, Michelle M. Le Beau, Manuel O. Diaz, and Janet D. Rowley

An identical reciprocal translocation between the long arms of chromosomes 3 and 21 with breakpoints in bands 3q26 and 21q22, t(3;21)(q26;q22), was found in three male patients with the blast phase of chronic myelogenous leukemia (CML). The abnormality was clonal in all three patients and was always accompanied by either a standard or variant 9;22 translocation resulting in a Philadelphia chromosome (Ph^1). In two cases, the t(3;21) was the only abnormality other than a t(9;22) in the primary clone. Serial studies of one patient demonstrated that the t(3;21) occurred as a result of clonal evolution near the time of development of the blast phase. We have not observed the t(3;21) in >500 patients with CML in the chronic phase. Thus, the t(3;21) is a new recurring cytogenetic abnormality associated with the blast phase of CML.

© 1987 by Grune & Stratton, Inc.

THE LEUKEMIA CELLS of virtually all patients with chronic myelogenous leukemia (CML) are characterized by the Ph^1 or Philadelphia chromosome, a product of a reciprocal 9;22 translocation, t(9;22)(q34;q11), or of a variant of this translocation.[1,2] The t(9;22) is present at the time of diagnosis of CML and throughout the course of the disease. Evidence is accumulating that the molecular consequence of this rearrangement, namely, fusion of sequences of the *ABL* and *bcr* genes, plays a critical role in the pathogenesis of CML.[3-5]

At diagnosis and during the chronic phase of CML, the t(9;22) is usually the sole cytogenetic abnormality; additional abnormalities are found in 9% to 30% of cases.[6-10] Subsequently, karyotypic evolution occurs in 80% of individuals before or during the blast phase.[9] Numerous secondary chromosomal abnormalities have been observed; however, only a few recurring abnormalities have been identified. The most common of these are +8, +Ph^1, and i(17q); at least one of these is found in 80% of individuals with evolution.[9,11] Rarely, specific abnormalities first identified in acute nonlymphocytic leukemia (ANLL) are noted. These include the t(15;17) of acute promyelocytic leukemia[12,13] and inv(3) and t(3;3) [also interpreted in some reports as an ins(3;3)] of ANLL with abnormal megakaryocytopoiesis[14-19]; in cases of CML with these abnormalities, the acute phase has the characteristic features of the corresponding ANLL.

We identified a new recurring cytogenetic abnormality in association with the blast phase of CML in three patients. This finding will provide a focus for molecular studies aimed at understanding the conversion of CML from chronic to blast phase.

MATERIALS AND METHODS

The patients we studied had been referred to the University of Chicago or Michael Reese Hospitals; specimens of bone marrow and/or blood were analyzed in the Hematology/Oncology Cytogenetics Laboratory. Each patient presented with clinical and morphological features typical of CML in the chronic phase. The diagnosis of CML was confirmed in all cases by identification of the Philadelphia chromosome in hematopoietic tissue. Morphological characterization of the blast phase was based on examination of peripheral blood smears and of bone marrow biopsy specimens and aspirates obtained before institution of acute phase therapy.

Cytogenetic analyses using trypsin-Giemsa, quinacrine fluorescence, and chromomycin-A_3-methyl green reverse fluorescence banding techniques were performed on bone marrow aspirates or peripheral blood samples. All three patients were studied during the blast phase; patient 1 was also studied during the chronic and accelerated phases. Metaphase cells from short-term (24-hour) unstimulated cultures and methotrexate-synchronized cells cultured for 48 hours in phytohemagglutinin (PHA)-stimulated leukocyte-conditioned medium were analyzed. The criteria first proposed by Rowley and Potter[20] and accepted at the First International Workshop on Chromosomes in Leukemia[21] were used for identification of abnormal clones. Chromosomal abnormalities were described according to the ISCN (1985).[22]

Southern blot analysis of DNA from patient 1 was performed as previously described[23]; we used DNA probes specific for the human transferrin receptor (*TFRC*) and Hu-*ets*-2 (*ETS2*) genes. The pTR48 probe contains ~1.6 kilobases (kb) of the 3′ untranslated region of a human *TFRC* cDNA clone[24]; the pTR1/7 probe contains 2.5 kb from the *TFRC* cDNA, including the entire coding region; and the pH33 probe contains 1.0 kb of human genomic sequences from the *ETS2* locus.[25]

RESULTS

Clinical and hematologic features. The clinical and hematologic features of the three patients who had CML and a t(3;21) are summarized in Table 1. All of the patients were men. Each had a relatively long chronic phase during which hydroxyurea and/or busulfan was administered. All three patients had splenomegaly, and patient 2 had lymphadenop-

*Bone marrow aspirates could not be obtained because of fibrosis; blast cell features were determined from peripheral blood samples, and megakaryocyte morphology could not be assessed fully.

athy. Patients 1 and 3 had an identifiable accelerated phase, during which patient 1 underwent splenectomy (spleen weight, 3.16 kg at removal) and patient 3 was treated with fluoxymesterone. Following onset of the blast phase, each patient died within 2 months despite vigorous attempts at remission induction.

Blast cells from the bone marrow (patient 1) or peripheral blood (patients 2 and 3) at the time of blast phase had a nonlymphoid morphology and were terminal deoxynucleotidyl transferase (TdT)-negative in each case. Patient 1 had a relatively high platelet count of 405×10^9/L during the blast phase, and his bone marrow and blood contained large numbers of micromegakaryocytes. The platelet count was not elevated in either of the other two patients.

Cytogenetic analyses. The results of cytogenetic analyses are summarized in Table 2 and are illustrated in Fig 1. Patient 1 was studied at three times during the course of his disease. The first study was performed during the chronic phase, 19 months following diagnosis. All 19 bone marrow cells examined had only a typical t(9;22)(q34;q11). The patient subsequently entered an accelerated phase characterized by weight loss and increasing splenomegaly, which was

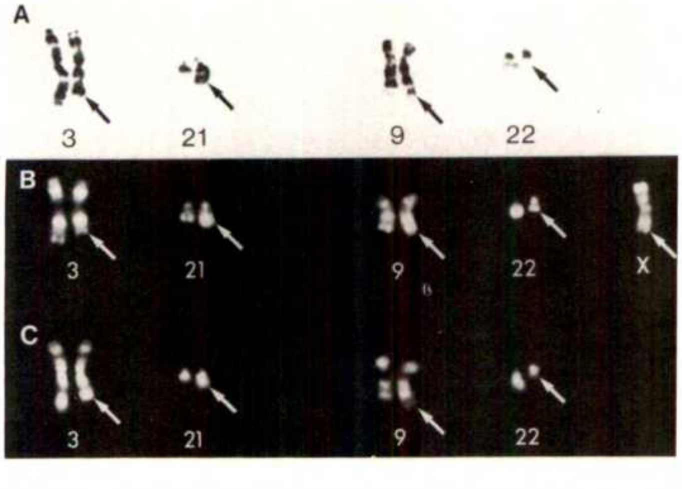

Fig 1. Partial karyotypes of three metaphase cells demonstrating the t(3;21) and the t(9;22) or t(X;9;22). The rearranged chromosomes are located on the right of each pair of homologs and are identified with arrows. (A) Patient 1: G-bands by trypsin using Giemsa. (B) Patient 2: R-bands by fluorescence using chromomycin-A$_3$-methyl green. (C) Patient 3: Q-bands by fluorescence using quinacrine.

refractory to systemic oral chemotherapy. Still, all 13 bone marrow metaphase cells studied had only a t(9;22). At the time of blast phase, however, two related pseudodiploid lines were present; 6 of 13 metaphase cells from the peripheral blood contained a t(9;22) as the only abnormality, and the remaining 7 contained a t(3;21)(q26;q22) in addition to the t(9;22).

Peripheral blood from patients 2 and 3 was studied in our laboratory at the time of blast phase. In patient 2, the predominant clone, comprising 21 of 22 metaphase cells studied, had 48 chromosomes. A three-way translocation, t(X;9;22)(p22;q34;q11), which is a variant of the standard t(9;22), was present. In addition, these cells had extra chromosomes 8 and 11, an isochromosome of the long arm of one chromosome 8 homolog, and a t(3;21)(q26;q22). The remaining cell had 49 chromosomes and contained these abnormalities as well as a second Ph^1. Three related subclones were found in patient 3; one was pseudodiploid and the other two were hyperdiploid. The simplest of these subclones had 46 chromosomes and had a standard t(9;22) and a t(3;21)(q26;q22) as the only abnormalities. The two other subclones had undergone further evolution, with one containing an extra chromosome 15 and a second Ph^1, and the other containing these abnormalities plus a deletion of a part of the long arm of one chromosome No. 7 [del(7)(q32q36)].

DNA analysis. At the cytogenetic level of resolution, the locations of the breakpoints of the t(3;21) at bands 3q26 and 21q22 correspond to the mapped positions of the *TFRC* gene[26] and of the human homolog 2 of the *ets* sequence of the transforming avian erythroblastosis virus E26 (*ETS2*),[27] respectively. To determine whether the *TFRC* or *ETS2* gene loci were rearranged as a consequence of the translocation, we performed Southern blot analysis of DNA from peripheral blood cells of patient 1; placental DNA was used as a control. DNA, which had been digested with *Eco*RI, *Hind*III, or *Pvu*II, was hybridized sequentially to two *TFRC* probes and an *ETS2* probe. The sample had been obtained at blast phase, concurrently with the sample used for cytogenetic analysis. The WBC count at that time was 86.4 × 10^9/L; of these cells, 41% were blasts and 36% were micromegakaryocytes. Only germline restriction fragments were detected with the probes. Thus, in this patient, there was no evidence for a translocation breakpoint within the *TFRC* or *ETS2* genes.

DISCUSSION

We identified an identical t(3;21)(q26;q22) in three male patients with Philadelphia chromosome-positive CML during blast phase. In one patient, whom we studied serially, we showed that the translocation has occurred in association with the development of the blast phase as the result of clonal karyotypic evolution. We have not observed a t(3;21) in >500 other patients with CML in the chronic phase (M. M. Le Beau and J. D. Rowley, unpublished observations). A review of the literature and of Mitelman's *Catalogue of Chromosome Aberrations in Cancer*[28] failed to reveal any other cases with a t(3;21)(q26;q22). One patient has been reported as having a t(3;21)(q12;q22) in the blast phase of CML[29]; however, the breakpoint on chromosome 3 differs from that in our cases. Thus, we have identified a new recurring abnormality associated with the blast phase of CML.

The t(3;21) is not entirely specific for CML, however; the same rearrangement has been observed as the only abnormality in bone marrow from two other patients studied in our laboratory, both of whom developed a myelodysplastic syndrome following cytotoxic chemotherapy for a prior malignancy (M. M. Le Beau and J. D. Rowley, unpublished observations). Because the t(3;21) is likely to be therapy induced in these two patients, the same abnormality found in the patients with CML may also be a result of exposure to mutagenic agents rather than a spontaneous evolutionary event. All three patients with CML and a t(3;21) had received chemotherapy during the chronic phase; two of these received the alkylating agent busulfan.

The breakpoints of the t(3;21) are of interest with respect to previously identified cytogenetic abnormalities in leukemia. The breakpoint in 3q26 corresponds to one of the breakpoints in the t(3;3)(q21;q26) and the inv(3)(q21q26), both of which are associated with ANLL and abnormal megakaryocytopoiesis.[15,16,30,31] Patient 1 had a high platelet count and numerous micromegakaryocytes in his bone marrow in the blast phase, reminiscent of the findings in ANLL patients with t(3;3) or inv(3). In contrast, patients 2 and 3 had low platelet counts and a marked reduction of morphologically identifiable megakaryocytes in the marrow at blast phase, suggesting that factors other than a breakpoint at 3q26 are important in determining the presence of megakaryocyte abnormalities. A breakpoint in 3q21, rather than 3q26, in the blast phase of CML has been proposed to be associated with a high platelet count and abnormal megakaryocytes. Bernstein et al reported two patients who had secondary cytogenetic abnormalities involving 3q21 at the time of blast phase of CML.[17] One had an inv(3)(q21q26) like that seen in ANLL, and the other had a t(3;9)(q21;q34); both had elevated platelet counts and numerous micromegakaryocytes at the time of blast phase. The common breakpoint in these two cases is 3q21. In the present report, the findings in patient 1 suggest that a breakpoint at band 3q26 without a 3q21 abnormality may also influence the megakaryocytes in certain cases; however, additional examples are needed for confirmation of this possibility.

The breakpoint in the t(3;21) at band 21q22 also corresponds to one breakpoint in another specific abnormality found in ANLL, namely, the t(8;21)(q22;q22).[32] The t(8;21) has not been identified in any reported cases of CML. Alimena et al, however, tabulated 256 breakpoints observed during blast phase of CML and found a cluster of eight occurring at 21q22,[33] suggesting that this may be an important site with respect to progression of CML.

By analogy to other recurring chromosomal rearrangements in human leukemia that have been studied at the molecular level, the consistency of the breakpoints in the t(3;21) implies that specific genes in bands 3q26 and 21q22 participate in this rearrangement. Furthermore, the t(3;21) may play an important role in disease progression. The latter is suggested by the absence of the t(3;21) during the chronic phase in patient 1 and by the presence of the t(3;21) at blast phase as the only chromosomal rearrangement other than the t(9;22) in the primary clone in patients 1 and 3. Therefore, an investigation of this abnormality at the DNA level might be helpful for an understanding of the basis for the conversion of CML from chronic to blast phase. Our initial approach has been to determine by standard Southern blot analysis whether *TFRC* or *ETS2*, which have been localized near bands 3q26[26] and 21q22,[27] respectively, was rearranged in DNA from patient 1. By using this method, we did not find abnormalities of either gene; however, new techniques such as pulsed-field gel electrophoresis, by which one can examine very large regions of DNA, may allow detection of rearrangements located farther away from these genes.[34]

ACKNOWLEDGMENT

We thank Dr James W. Vardiman for his assistance in the morphological review of of these cases; Drs Claudio Schneider and Takis S. Papas for supplying the *TFRC* and *ETS2* probes, respectively; Marjorie Isaacson for data management; Paulette Martin, Mary E. Neilly, and Mariann Coyle for technical assistance; Leslee Snyder for photographic assistance; and Elisabeth Lanzl for editorial comment. We thank the following physicians for referring the patients who are included in this study to the University of Chicago: Drs W. D. Pletcher, C. M. Shapiro, S. C. Weil, and J. N. Winter.

Recombinant Gibbon Interleukin 3 Supports Formation of Human Multilineage Colonies and Blast Cell Colonies in Culture: Comparison With Recombinant Human Granulocyte-Macrophage Colony-Stimulating Factor

By Anne G. Leary, Yu-Chung Yang, Steven C. Clark, Judith C. Gasson, David W. Golde, and Makio Ogawa

The genetic sequences encoding the gibbon and human interleukin 3 (IL 3) proteins were molecularly cloned. The amino acid sequence of the mature gibbon IL 3 protein proved to share 93% homology with the corresponding human protein. We examined the effects of biosynthetic (recombinant) gibbon IL 3 on the proliferation and differentiation of an enriched population of human hematopoietic progenitors and compared the results with the effects of recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF). Gibbon IL 3 supported the formation of various types of single lineage as well as multilineage colonies by My-10$^+$ bone marrow cells in the presence of human erythropoietin (Ep). In contrast, recombinant human GM-CSF supported the formation of single-lineage colonies and only a small number of multilineage colonies. Both IL 3 and GM-CSF had significant erythroid burst-promoting activity (BPA). Delayed addition of gibbon IL 3 to low serum culture of My-10$^+$ marrow cells supported the formation of blast cell colonies with variable but high replating capability. Human GM-CSF was less effective than IL 3 in support of multipotential blast cell colonies. These results are analogous to the effects of murine IL 3 and GM-CSF on murine progenitors and support the notion that the primary factor for multipotential progenitors is IL 3.

HEMATOPOIETIC CELL proliferation and differentiation in semisolid culture is supported by protein/glycoprotein hormones called colony-stimulating factors (CSFs). CSFs are produced by a variety of tissues and include CSF-1, a macrophage CSF,[1] granulocyte-macrophage CSF (GM-CSF),[2] granulocyte CSF (G-CSF)[3] and interleukin 3 (IL 3).[4] These CSFs have been purified, and the genes encoding the proteins have been molecularly cloned. Whereas CSF-1 and G-CSF act primarily on monopotent progenitors, murine IL 3 and GM-CSF have been reported to support proliferation of multipotential progenitors. Murine IL 3 was purified by Ihle et al[4] in 1982 and subsequently was shown to support formation of multilineage colonies[5] and blast cell colonies in culture.[6,7] Recently, the genes for gibbon and human IL 3 were identified using expression cloning techniques, and the gibbon IL 3 has been expressed in Cos-1 monkey cells.[8] Comparison of the amino acid sequences of the human and gibbon proteins revealed that they are 93% homologous.[8] This extensive homology suggests that gibbon and human IL 3 may be functionally similar.

Using granulocyte-macrophage colony formation in agar as an assay, murine GM-CSF was initially purified from medium conditioned by mouse lung tissue.[2] Subsequent studies carried out by Metcalf et al[9] and in our laboratory[10] suggested that it is capable of supporting proliferation of multipotential progenitors. Emerson et al[11] reported that human GM-CSF supports proliferation of multipotential progenitors. In this report, we examined the effects of gibbon recombinant IL 3 on hematopoietic colony formation by highly enriched human bone marrow cells and compared the results with the effects of human recombinant GM-CSF in culture.

MATERIALS AND METHODS

Recombinant factors. The recombinant gibbon IL 3 used in this study was obtained by transfecting monkey Cos-1 cells with gibbon IL 3 cDNA clone, pCSF-MLA.[8] Five micrograms of pCSF-MLA DNA was used to transfect a 100-mm dish of Cos-1 cells by diethylaminoethanol (DEAE) Dextran–mediated DNA transfection with the addition of 0.1 mmol/L chloroquine.[12,13] Conditioned media (CM) from transfected Cos-1 cells were harvested 72 hours after transfection. The concentration of IL 3 was estimated to be 100 nmol/L according to the bioassay developed by Griffin et al.[14]

Human GM-CSF was purified as previously described[15,16] from serum-free medium conditioned by monkey Cos-1 cells transfected with human GM-CSF cDNA clone, p91023(B). The purified GM-CSF appeared as a single protein band of 22,000 mol wt on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), the same mol wt as the purified natural GM-CSF.[15] Protein concentration was estimated by amino acid analysis.

Methylcellulose cell culture. Bone marrow cells were aspirated from the posterior iliac crest of healthy adult volunteers and placed in 16-mL Falcon tissue culture tubes containing 400 U of preservative-free heparin (Invenex Laboratories, Melrose Park, IL). The donors were advised of the risks of marrow aspiration and gave informed consent. These studies were approved by the Institutional Review Board for Human Research. Mononuclear cells were isolated by use of Ficoll-Paque (Pharmacia, Piscataway, NJ), and the nonadherent fraction was separated by overnight adherence to plastic. Samples were further enriched for colony-forming cells by positive indirect immune adherence using human progenitor cell antibody (HPCA) (Becton Dickinson, Mountain View, CA) which is the commercial preparation of monoclonal anti–My-10 antibody,[17] and the "panning" technique of Engleman et al.[18] Details of this procedure have been reported previously.[17]

Panned My-10$^+$ bone marrow cells were cultured in 35-mm Lux suspension culture dishes (Miles Laboratories, Naperville, IL) using a modification of the technique of Iscove et al.[19] One milliliter of

culture consisted of 2,000 My-10$^+$ bone marrow cells, α-medium (Flow Laboratories, Rockville, MD), 1.2% of 1,500 centipoise methylcellulose (Fisher Scientific, Norcross, GA), 30% fetal calf serum (FCS) (Flow Laboratories), 1% deionized bovine serum albumin (BSA) (Sigma Chemical, St Louis), 5×10^{-5} mol/L mercaptoethanol, 2 U/mL human urinary erythropoietin (Ep) with a specific activity of 370 U/mg protein (kindly provided by Dr Makoto Kawakita, Kumamoto University School of Medicine, Japan) and variable concentrations of IL 3 and GM-CSF. Dishes were incubated at 37°C in a humidified atmosphere of 5% CO_2 in air. On days 14 through 16 of incubation, the types and sizes of the colonies were estimated in situ. Abbreviations for colony types were: GM, granulocyte and/or macrophage colonies; Meg, megakaryocyte colonies; Eo/Baso, eosinophil and/or basophil colonies;[20] E, erythroid bursts; and E-mix, mixed colonies containing erythroid cells. When cytologic confirmation was required, colonies were individually lifted from methylcellulose by an Eppendorf micropipette and slides were prepared using a cytospin centrifuge (Shandon Southern Instruments, Sewickley, PA). Slides were stained with May-Grunwald-Giemsa (Gallard Schlesinger Chemical, Carle Place, NY) for differential counting.[21]

Blast cell colony formation. The factors were also tested for their capacity to support blast cell colony formation using a technique we developed recently.[22] In brief, 1×10^4 panned My-10$^+$ bone marrow cells were plated in methylcellulose culture containing: α-medium; 2% FCS; 1% crystallized, deionized BSA; 5×10^{-5} mol/L mercaptoethanol; and 300 μg/mL fully iron saturated human transferrin (98% pure) 160 μg/mL soybean lecithin 96 μg/mL cholesterol, and 10^{-7} mol/L sodium selenite (Sigma). On day 14 of incubation, 0.1 mL of a 1:50 dilution of IL 3 or 10 or 1 nmol/L GM-CSF was layered over the culture, and the dishes were examined daily for the appearance of blast cell colonies between days 21 and 32.

When identified, blast cell colonies were replated in culture for confirmation of their ability to form secondary colonies. For these experiments, blast cell colonies were individually lifted from the culture and suspended in 100 μL α-medium. The samples were gently pipetted and then added to 0.9 mL methylcellulose medium containing 30% FCS, 1% deionized BSA, 2 U/mL Ep, and 30% C5MJ CM.[22] Cultures were incubated at 37°C and 5% CO_2 in air. When colonies appeared to have matured (generally after 12 to 16 days of culture), individual colonies were prepared for differential counting as descibed above.

RESULTS

Colony formation supported by IL 3 and/or GM-CSF. First, we carried out titration of IL 3 for colony formation in culture. Two thousand My-10$^+$ marrow cells were plated in cultures containing different dilutions of IL 3 preparations and 2 U/mL Ep. As controls, cultures were also prepared with conditioned medium from nontransfected Cos-1 cells (mock) plus Ep, C5MJ CM plus Ep, or Ep alone. C5MJ supports a wide variety of colony types, including mixed colonies.[22] The results are presented in Table 1. IL 3 preparations ranging from 1:50 dilutions to 1:5,000 dilutions supported formation of various types of single lineage as well as multilineage colonies. Although the number of colonies supported by three different dilutions of IL 3 were similar, the colonies were smaller in the 1:5,000 dilution of IL 3 than those grown in higher concentrations of IL 3. Most notably, the largest colonies in all categories were smaller in 1:5,000 dilutions than in 1:500 dilutions. Based on these observations, the 1:500 dilution was chosen as the standard concentration. The concentration of IL 3 in this dilution was estimated to be 200 pmol/L (described in the Materials and Methods section). The mock CM plus Ep or Ep alone supported only occasional GM colonies or clusters in the My-10$^+$ fraction of cells.

In the next experiment, My-10$^+$ marrow cells were plated in quadruplicate cultures in the presence of Ep, GM-CSF, and/or IL 3. The results are presented in Table 2. To confirm that 100 pmol/L GM-CSF is the optimal concentration for colony formation, marrow cells were cultured in five different concentrations of GM-CSF. As has been shown by Tomonaga et al,[23] this concentration of GM-CSF was the optimal concentration for colony formation. A 1:500 dilution (~200 pmol/L) of IL 3 and Ep supported formation of various types of colonies, including E-mix colonies. A representative mixed colony containing macrophages, eosinophils, and erythrocytes is shown in Fig 1. In contrast, GM-CSF rarely supported formation of E-mix colonies. As demonstrated by a number of investigators,[24-26] GM-CSF in all concentrations augmented formation of erythroid bursts in culture. Mock CM and Ep failed to support formation of erythroid bursts.

Cytologic analysis of lineage expression. For determination of the precise lineages expressed in the colonies in culture, 2,000 My-10$^+$ marrow cells were plated in each dish with IL 3 plus Ep or GM-CSF plus Ep, and on days 14 through 16 of incubation, colonies in each group were individually analyzed for their cellular composition. The results are presented in Table 3. In two separate experiments, most colonies supported by GM-CSF were single-lineage colonies. A 100-fold increase in the concentration of GM-

*Concentration of IL 3 was estimated to be 200 pmol/L.

CSF showed no difference in the number and types of colonies. IL 3 plus EP supported formation of many types of multilineage colonies, including pentalineage colonies. In contrast, only a few mixed colonies were supported by GM-CSF plus Ep.

Blast cell colony formation. In 8 experiments using 8 separate marrow samples, 67 blast cell colonies were identified in 50 culture dishes receiving delayed addition of IL 3. Thirty-one of 48 replated blast cell colonies yielded secondary colonies in the presence of C5MJ CM plus Ep. The size of blast cell colonies ranged from 21 cells to 41 cells/colony, and the percentage of replating efficiencies of the positive colonies ranged from 11% to 65%. As shown in Table 4, secondary colonies included single-lineage colonies such as neutrophil (n), macrophage (m), eosinophil (e), basophil (b), or erythrocyte (E) colonies as well as many bilineage and trilineage colonies. Occasional tetralineage secondary colonies revealed all four leukocyte lineages. Two concentrations of GM-CSF were tested for their ability to support blast cell colony formation. When 13 blast cell colonies were replated in C5MJ CM plus Ep, only two colonies produced secondary colonies revealing n, m, or nm lineages. When a tenfold higher concentration of GM-CSF was used, four of ten blast cell colonies produced secondary colonies, including eosinophil colonies. Most blast cell colonies supported by GM-CSF apparently do not possess significant proliferative capacity and probably consist of progenitors committed only to the n, m, and e pathways.

DISCUSSION

Despite extensive search by a number of investigators, the gene for human IL 3 eluded identification until recently. Using ^{3}H-labeled thymidine uptake by blast cells from patients with chronic myelogenous leukemia[14] as an assay in expression cloning, an IL 3 gene was identified from a cDNA library prepared from a gibbon lymphosarcoma cell line.[8] This gibbon cDNA was used as a probe to identify and clone the gene for human IL 3.[8] The nucleotide sequence of the coding region of gibbon IL 3 proved to share 96% homology with the human IL 3 sequence.[8] From this observation it was deduced that the protein from the two species differ by 11 amino acids, 9 of which reside in the mature protein sequence. We found gibbon IL 3 to be active on purified human progenitors. The results presented in this article suggest that the function of gibbon IL 3 will be similar to human IL 3 since in the presence of Ep gibbon IL 3 supported formation of all types of single-lineage colonies, multilineage colonies, and multipotential blast cell colonies.

A controversy exists regarding the targets of murine and human GM-CSF. Murine GM-CSF was originally consid-

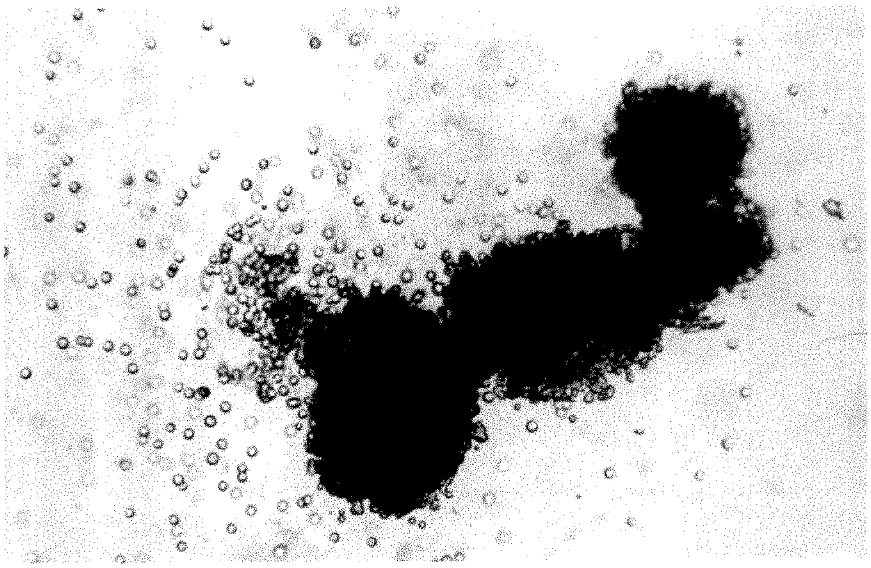

Fig 1. A typical mixed colony supported by IL 3 contains macrophages, eosinophils, and erythrocytes.

All colonies in a single dish containing 2,000 My-10$^+$ cells were individually analyzed.

ered specific for the GM pathways. Most recently, Kajigaya et al[27] reported that recombinant murine GM-CSF is restricted to the GM pathways. In contrast, Metcalf et al in 1980[9] reported that purified murine GM-CSF supports a few cell divisions of multipotential progenitors. They also demonstrated that very high concentrations of recombinant murine GM-CSF support formation of eosinophil colonies, macrophage colonies, and E-mix colonies.[28] Recently, we showed that murine GM-CSF supports formation of multipotential blast cell colonies.[22] Comparison with the blast cell colony formation supported by IL 3, however, suggested that the progenitors for the blast cell colonies that respond to GM-CSF represent only a subpopulation of those responding to IL 3.

Human GM-CSF is generally believed to support proliferation and maturation of neutrophil, macrophage, and eosinophil progenitors.[23,29] Controversy exists regarding additional functions of human GM-CSF in hematopoiesis. Investigators at Harvard University[11,24,25] reported that human GM-CSF is capable of supporting multilineage colony formation and possesses significant erythroid burst potentiating activity (BPA). In contrast, Metcalf et al[29] reported only minimal amounts of such activities. We have shown that human GM-CSF and human Ep supports formation of all types of single-lineage colonies, including basophil and megakaryocyte colonies. Our data corroborated those on human GM-CSF of Kaushansky et al[26] regarding the support for megakaryocyte colony formation. Our observation also corroborates the observation by Donahue et al[24] and Sieff et al[25] that human GM-CSF possesses significant BPA in vitro. The observed phenomena may not be solely due to the direct action of human GM-CSF because the culture media contained FCS, Ep, and BSA. Although My-10$^+$ bone marrow cells were highly enriched for progenitors, they were not a pure population of progenitor cells.

Both IL 3 and GM-CSF supported formation of multilineage colonies. Cytologic examination of individual colonies revealed, however, that gibbon IL 3 is far more effective

Table 4. Summary of Blast Cell Colony Formation by IL 3 or GM-CSF

Factor	Incidence of Blast Cell Colonies	Positive Colonies in C5MJ	Plating Efficiency	Lineages in Secondary Colonies
IL 3*	67 colonies/51 dishes	31/48	11%-65%	n, m, e, b, E, nm, me eb, eE, mE, meE, nmeb
GM-CSF (100 pmol/L)	19 colonies/40 dishes	2/13	14%-20%	n, m, nm
GM-CSF (1 nmol/L)	10 colonies/20 dishes	4/10	18%-63%	n, m, e, nm

*Concentration of IL 3 in each dish was a 1:500 dilution, which is ~200 pmol/L.

than human GM-CSF in supporting the proliferation of multipotential progenitors. Whereas a number of multipotential blast cell colonies were identified in cultures receiving delayed addition of IL 3, fewer blast cell colonies were supported by GM-CSF and yielded secondary colonies. The secondary colonies were restricted to neutrophil, macrophage, and eosinophil lineages. These observations are analogous to the reported results of murine factors on multipotential progenitors.[9,10] Our previous data suggested that the progenitors for murine blast cell colonies responding to murine GM-CSF represent only a subpopulation of those responding to murine IL 3.[10] Human multipotential progenitors that respond to GM-CSF may also represent a small subpopulation of multipotential progenitors sensitive to IL 3.

ACKNOWLEDGMENT

We thank Geneva Winker, Sharlotte Kovacic, JoAnn Giannotti, Agnes Ciarletta, and Susan Kaufman for their excellent technical assistance. We also thank Pamela N. Pharr and Linda S. Vann for their assistance in the preparation of this manuscript.

Molecular Characterization of Chromosome 7 Long Arm Deletions in Myeloid Disorders

By Juha Kere, Tapani Ruutu, Reino Lahtinen, and Albert de la Chapelle

Partial deletion of the long arm of chromosome 7 is a common abnormality in the bone marrow cells of patients with myelodysplastic syndrome (MDS) or acute nonlymphocytic leukemia (ANLL). This study was undertaken to characterize the chromosome breakpoints in molecular terms and to determine if hemizygosity or submicroscopic deletions occur in patients without any cytogenetically detectable abnormality of chromosome 7. We studied restriction fragment length polymorphisms with 10 chromosome 7-specific DNA probes in separated WBC fractions. No molecular abnormalities occurred in lymphocyte-derived DNA. Several probes located in band 7q22 or distally thereof detected deletion of one allele in granulocyte-derived DNA from all four patients with chromosome 7 long arm deletion. In the granulocytes of one patient heterozygosity for the T cell receptor β chain gene (in band 7q35) indicated that the deletion was interstitial. NJ-3, a proalpha2(I)collagen gene probe (in band 7q21-22) detected heterozygosity in the granulocytes of one patient. No hemizygosity or deletions were found in four patients with two normal chromosomes 7. These results confirm that mature granulocytes but not lymphocytes are derived from the abnormal clone. Interstitial deletions exist, and the extent of deleted genomic material varies among patients.

PARTIAL DELETION of the long arm of one chromosome 7 is a common recurrent chromosome abnormality in secondary myelodysplastic syndrome (MDS) or acute nonlymphocytic leukemia (ANLL). The abnormality is often designated as del(7)(q22) implicating terminal deletion with breakage in band q22, but other breakpoints and interstitial deletions have been described in many patients.[1,2] In molecular terms, however, the deletions have not yet been characterized. Development of hemizygosity has been demonstrated in solid tumors as a mechanism possibly contributing to the tumorigenesis.[3-8] In this article, we address two questions: First, can the cytogenetically observed deletions be further characterized with molecular methods, and second, can hemizygosity be observed in patients with two cytogenetically normal chromosomes 7. We previously demonstrated that in MDS or ANLL monosomy 7 or partial deletion of the long arm can be detected in blood granulocytes or monocytes with restriction fragment length polymorphism (RFLP) analysis.[9] In the present study, we tested 10 DNA probes located in different parts of chromosome 7 for their presence or absence in each of the two chromosomes 7. We studied four patients with a 7q− chromosome to characterize the chromosomal breakpoints in molecular terms, and four patients with two apparently normal chromosomes 7 to determine if development of hemizygosity or deletions can be detected. Our results provide basic knowledge about the chromosomal breakpoints in molecular terms and confirm heterogeneity of the 7q− chromosome in myeloid disorders.

MATERIALS AND METHODS

Patients and cytogenetic studies. Eight patients with a hematologic disorder were studied (Table 1). The study was approved by the ethics committee of the Department of Medical Genetics, University of Helsinki. Cytogenetic studies of blood and bone marrow specimens were performed using standard techniques and Giemsa banding as previously described.[13]

Specimens and cell separation. Blood (10 to 40 mL) was diluted with phosphate-buffered saline (PBS) solution, and the mononuclear cells were separated from granulocytes and RBCs within 24 hours of sampling by Ficoll density-gradient centrifugation.[14] The lymphocyte and granulocyte fractions were recovered as described.[9] Purity of the cell fractions was checked from smears or cytocentrifuge preparations stained with May-Grünwald-Giemsa or Sudan black B.

DNA probes and molecular studies. High-mol-wt DNA was extracted separately from each of the blood cell fractions. A standard proteinase K digestion, phenol extraction, and ethanol precipitation procedure was used.[15] The RFLP analysis was done using previously published methods with minor modifications.[16] For each experiment, 3 to 5 μg DNA was digested with a restriction enzyme according to the instructions. Whole blood DNA samples from healthy subjects were included in each experiment as controls. Completeness of the digests was confirmed by staining the gels with ethidium bromide. Nitrocellulose filters (Schleicher & Schuell, Dassel, FRG) were used in Southern blotting. Nick-translation of the DNA probes was done using an Amersham N.5000 kit. Hybridization was at 65°C for 19 to 24 hours. The autoradiograms were scanned using a laser densitometer (LKB 2202 Ultroscan, Bromma, Sweden) to quantitate the strength of the allelic bands.

The chromosome 7-specific DNA probes used in this study are listed in Table 2. All patients were tested for RFLPs using whole blood-, lymphocyte-, and granulocyte-derived DNA samples.

RESULTS

Cytogenetic studies. By conventional cytogenetic analysis of bone marrow mitoses, patients 1 through 4 each had a partial deletion of chromosome 7 in addition to other abnormalities (Table 1, Fig 1). In patients 1 and 2, only the abnormal clone was found; in patients 3 and 4, mitoses with a normal karyotype also occurred. Patients 5 through 8 had

*Patient 1 had PV; patients 3 and 4 were previously treated for lymphoma.

other chromosomal abnormalities in the bone marrow but two apparently normal chromosomes 7. In patients 3 and 4, the deletion was cytogenetically compatible with the designation del(7)(q22); this implies a terminal deletion, but the presence or absence of a telomeric piece cannot be definitely ascertained. In patient 2, the deleted chromosome looks longer and could be interstitial with breakpoints at 7q22 and q33-34. In patient 1, the deletion also appeared different and an interstitial deletion del(7)(pter → q21::q32-35 → qter) was suspected. To accommodate the uncertainty as to the cytogenetic definition of the breakpoints, all partially deleted chromosomes 7 were designated 7q−. Phytohemagglutinin (PHA)-stimulated blood mitoses were normal in all patients.

Purity of separated cell fractions. The mononuclear nonadherent cell ("lymphocyte") fraction contained 80% to 96% lymphocytes in different experiments. In the granulocyte fraction 66% to 99% of the nucleated cells were neutrophils in different experiments. The fractions were cross-contaminated; <9% erythroblasts were present in the lymphocyte fractions. The purity of each sample is given in the legend to Fig 2.

RFLP heterozygosity. All patients were heterozygous for at least one polymorphism. The constitutional RFLP alleles are shown in Table 3. No differences were observed between the whole blood-, lymphocyte-, and granulocyte-derived DNA samples from patients 5-8.

Missing RFLP alleles in patients with deletions. One of the *MET* oncogene alleles was very weak or almost absent in the granulocyte fractions of patients 1 through 3 as detected by the MetH probe. In patient 4, the 1.7-kilobase (kb) allele detected by probe J3.11 was very weak in the granulocyte fraction. Marked reduction in the intensity of one of the allelic bands in the granulocyte fraction was also observed with probe B79a in patients 1 and 2, with probe 7C22 in patients 2 and 3, with probe hR-II in patient 2, and with probe TCRB in patient 1. The visual impression was confirmed by densitometry in all cases. The allelic bands of patient-derived DNA samples were compared with those of healthy controls, and the reduction in intensity was 69% to 98% (35% to 62% with probe 7C22) in different samples. In the whole blood-derived DNA, the weaker allele was always stronger than in the granulocyte DNA but weaker than in the lymphocyte DNA. In contrast, two alleles of normal strength were observed in the granulocyte-derived DNA samples of patients 1 and 3 with probe ASSpC7 (located in the short arm), of patient 2 with probe NJ-3, and of patient 1 with probe TCRB. The results are shown in Fig 2. No unexpected hybridization bands suggesting rearrangements were observed.

DISCUSSION

Loss of an RFLP allele in the malignant tissue has been previously observed in several tumors and hematologic malignancies.[3-9,29] The loss may be due to monosomy or deletion of part of a chromosome or to hemizygosity without visible cytogenetic changes on the molecular level. Weakness or absence of chromosome 7-specific RFLP alleles was observed in all four patients with a 7q− chromosome. In contrast, none of the four patients with two apparently normal chromosomes 7 showed weakness of one allele. These results are compatible with the cytogenetic analyses of bone marrow and PHA-stimulated whole blood cultures. We conclude that loss of alleles in the granulocyte fractions was due to the presence of a 7q− chromosome in most if not all of the blood granulocytes. Weakness instead of absence of allelic bands in the granulocyte-derived samples was probably due to contamination of the granulocytes with other blood cells with two chromosomes 7 as shown by the cytologic stainings (described in legend to Fig 2). Another explanation is the coexistence of subsets of granulocytes with

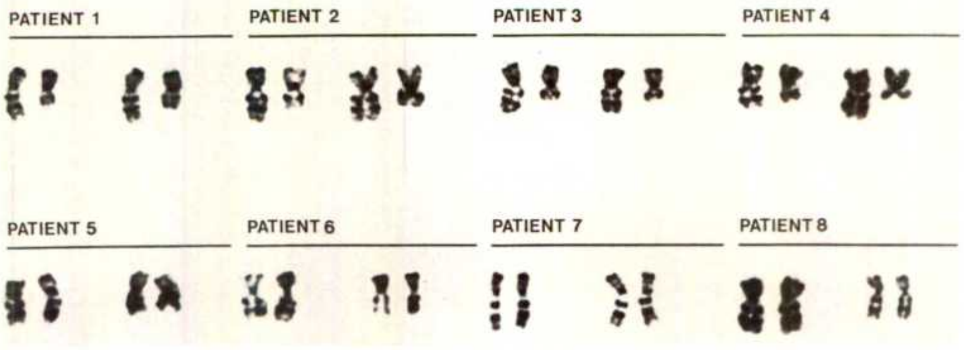

Fig 1. Partial karyotypes showing G-banded chromosomes 7 from two bone marrow cells. Patients 1 through 4 have a partial deletion of the long arm of one homolog of chromosome 7. In patient 1, the deletion could be interstitial del(7)(pter → q21::q32-35 → qter); in patient 2, a different interstitial deletion is possible; in patients 3 and 4, the appearance is compatible with a terminal deletion del(7)(q22). Patients 5 through 8 have two structurally normal chromosomes no 7.

Numbers indicate alleles: 1 corresponds to larger fragment, 2 (or 3) to smaller fragment (fragment sizes given in Table 2). ND, not determined.

and without a deleted chromosome 7, which may be quite likely in patient 3 who had both cytogenetically normal and abnormal mitoses in the bone marrow (Table 1).

Acquired hemizygosity or homozygosity was not observed with various chromosome 7-specific markers in patients with two structurally normal chromosomes 7. This can be interpreted to suggest that molecular changes did not occur in chromosome 7 in these patients. Distinct molecular changes involving relevant genes may be present, however, but are not necessarily detectable with these probes. Two genes that regulate the function of hematopoietic tissue (erythropoietin and platelet-derived growth factor) have been mapped to chromosome 7[30,31] and others may still be undetected. The nature of the genes on chromosome 7 that may play a role in the development of MDS or ANLL is unknown at present.

Proximal breakpoint. The *MET* oncogene locus and the anonymous probes J3.11 and B79a have all been mapped to band 7q22.[21-23] These loci were deleted in all informative patients with a 7q− chromosome. Provided that the cytogenetic analysis correctly defines the breakpoint to 7q22, our results suggest that these probes are in the distal part of that band. Probe 7C22 was originally localized more distally (band q31) but closely linked with the cystic fibrosis locus.[24] In the granulocyte fraction of patients 2 and 3, however, one allelic band detected by probe 7C22 was weak but unexpectedly strong in comparison with the weaker allele detected by probes MetH or B79a. We have been unable to find a satisfactory explanation for this observation.

Probe NJ-3 detected two allelic bands of equal intensity in the lymphocyte and granulocyte fractions in patient 2 in whom deletion was detected with probes B79a, MetH, 7C22, and hR-II. The simplest interpretation is that the locus detected by probe NJ-3 is proximal of the other loci and not included in the deletion in this patient, which is in accordance with the published localization of the probes,[20-24] and with our cytogenetic interpretations (Table 1, Fig 1). All these loci are linked to the cystic fibrosis locus and map to a relatively short segment on the long arm of chromosome 7.[20-24]

Distal breakpoint. Assuming that not all deletions are terminal,[2] a distal breakpoint must also be defined. The T cell receptor β chain gene (*TCRB*) is located in band 7q35, and probe hR-II is closely linked to the *TCRB* locus.[25-27] Patients 1 and 3 were heterozygous for the TCRB polymorphism, and patient 2 was heterozygous for the hR-II polymorphism. In patient 3, one of the two allelic bands detected by the TCRB probe was very weak in the granulocyte derived sample. A similar finding was obtained with patient 2 using the hR-II probe. These results are compatible with the deletion extending distally of *TCRB* and *hR*-II, but do not necessarily imply a terminal deletion. Patient 1, however, showed two equally strong allelic bands with the TCRB probe in both lymphocyte and granulocyte fractions. The most simple interpretation is that an interstitial segment of the chromosome has been deleted and the terminal part including *TCRB* has been retained in patient 1. These results are in agreement with the cytogenetic results that show an interstitial deletion. We conclude that the 7q− chromosomes were different in terms of deleted genomic material in different patients and that interstitial deletions exist.

ACKNOWLEDGMENT

We thank the following investigators for probes used in this study: A. Beaudet, T. Jahnsen, M. Minden, W. O'Brien, J. Schmidtke, J. Seidman, P. Tsipouras, G. Vande Woude, and R. Williamson. We thank Professor R. Williamson and the London cystic fibrosis research group for helpful discussions.

Shear Stress Activation of Platelet Glycoprotein IIb/IIIa Plus von Willebrand Factor Causes Aggregation: Filter Blockage and the Long Bleeding Time in von Willebrand's Disease

By J.R. O'Brien and G.P. Salmon

The article explores the finding that high shear alone applied to normal, native blood results in platelet aggregation. A filter with tortuous capillary-sized channels permits a study of the effect of shearing forces at different pressures. Native, heparinized, citrated and EDTA blood and platelet-rich plasma (PRP) were forced through the filter. Normal and von Willebrand's blood were studied, as were the effects of antibodies to platelet glycoproteins (GPr) and to von Willebrand's factor (vWf) and of "membrane-active" drugs. Normally, the filter blocked at 40 mmHg but not at 5 mmHg. Transmission electronmicroscopy of the filter at 40 mmHg showed blockage by platelet aggregates. Initially, the mean transit time through the filter was 8 milliseconds. Platelet retention in the filter occurred in two phases. From 0 to 3 seconds, only high-shear, vWf, and GPrIIb/IIIa were required. From 10 to 20 seconds, retention presumably involved these three attributes, but divalent cations were also essential. Only this phase was inhibited by some membrane-active drugs. ADP- and thrombin-induced aggregation requires GPrIIb/IIIa and fibrinogen. Shear-induced blocking of the filter by blood with a normal concentration of fibrinogen requires GPrIIb/IIIa and vWf. This indicates a different type of exposure of GPrIIb/IIIa. The long bleeding time in vW disease highlights the absolute requirement for vWf and emphasizes the difference in exposure of GPrIIb/IIIa induced by shear stress. Evidently, a process similar to that occurring in the filter is required in normal capillary hemostasis.

THE LONG TEMPLATE bleeding time at 40 mmHg in von Willebrand's disease (vWd) is not fully understood. Ristocetin apart, vW platelets behave normally in most tests, but abnormalities are regularly reported in conditions of high shear.[1-8] This article explores the paradox that with high shearing forces, when it must be difficult to secure hemostasis, von Willebrand's factor (vWf) is required. At low pressure, evidently other mechanisms are involved.

If native blood is forced through a polycarbonate Nuclepore filter with 5-μm holes, only a few single platelets adhere to the upper surface. Thus, the material is relatively inert. On the underside, massive clumps of platelets are deposited.[9,10] Sheared platelets will aggregate and block small holes[11,12] and filters.[13-15] A thin filter with tortuous capillary-sized channels permitted a detailed study of the effects of the shearing forces necessary to produce platelet aggregates that are retained and block the filter.

MATERIALS AND METHODS

The device is shown diagrammatically in Fig 1. The commercial filter is made of glass fibers 0.1 to 3.4 μm in diameter; they run in all directions (Fig 2), creating tortuous channels of varying geometry through the filter. Particles >10 μm in diameter are retained. The filter, effectively 9 mm in diameter, is held in a filter holder (Nuclepore, Pleasanton, CA). The basic method is as follows. Modifications are outlined in the Results section. First, with tap Y closed, the air reservoir is filled to the required pressure through X. The blood syringe, a 2-mL (sometimes a 5-mL) routine plastic syringe is modified by passing a 16-gauge butterfly needle through the rubber flange of the plunger, which remains in the fully extended position. Blood, 2 or 5 mL, is aspirated into this syringe by suction, with another syringe attached to C in tap Y. A loaded filter holder is attached to the blood syringe, and the assembly is clamped over the drop counter. A is connected to B, and the blood is forced through the filter. The first effluent drop triggers a timer and drop counter, and the cumulative drops at 5-second intervals are recorded manually. The effluent drops during the first 3 seconds, and those emerging between 10 and 20 seconds are collected into EDTA tubes.

The cumulative drop count can be plotted against time (Fig 3). A measure of the progressive rate of slowing—the "drop ratio"—is obtained by dividing the average number of drops/5 sec recorded between 10 and 20 seconds by the initial rate [(drops 10 to 20/2)/drops 0 to 5] × 100. Thus, a high ratio indicates little slowing.

Platelets and WBCs are then counted in the initial blood or platelet-rich plasma (PRP), in the 0- to 3- and the 10- to 20-second samples. From these, the percentage of cells retained is calculated and, since the the volume of blood at blockage is known (20 drops = 1 mL), the absolute number of platelets required to block the filter can be calculated.

The standard procedure, unless otherwise specified, was as follows. Nine milliliters of blood, collected by a perfect venipuncture, were delivered into a polystyrene/polypropylene tube (no. Z10PS/NL, Sterilin, Feltham, Middlesex, England) in which was 1 mL saline containing 40 IU heparin (Weddel, Wrexham, England). Aliquots tested within 2 hours gave results similar to those tested immediately provided that the blood was stored at room temperature and thoroughly mixed for 5 minutes to eliminate RBC rouleaux formation. The capped tubes contained 2 mL air, so that any pH change was small and constant. The pressure normally was 40 mmHg, and observations were continued until all the blood had run through or until the filter blocked, which is defined as ≤1 drop/5 sec.

An unused filter was visualized by scanning electronmicroscopy (SEM) (Fig 2). For transmission electronmicroscopy of the filters after passage of blood or PRP, the filtration was stopped after a predetermined time; the filter was removed and plunged within 10 seconds into 2.5% glutaraldehyde in 0.1 mol/L sodium cacodylate, postfixed in osmium tetroxide, dehydrated, and embedded in Spurr's resin. Despite the glass fibers, routine sections were satisfactory and were stained with uranyl acetate and Reynold's lead acetate.

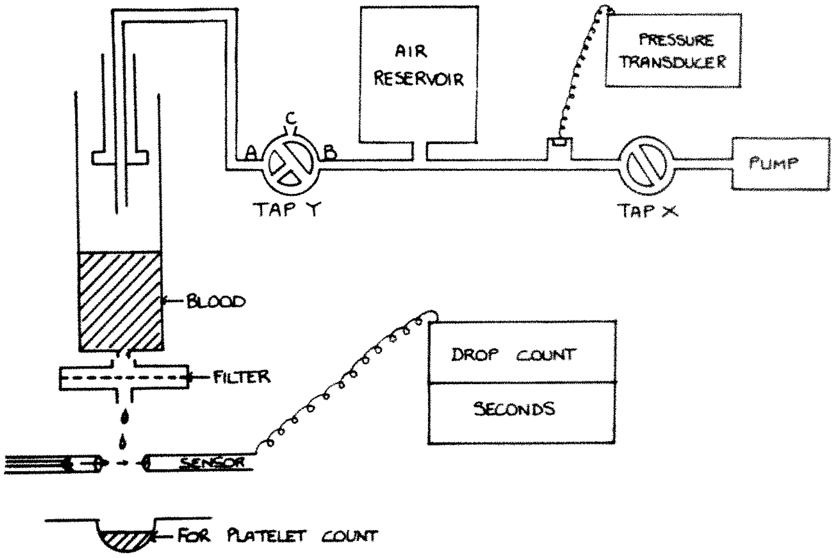

Fig 1. Diagrammatic representation of the device.

Chemicals and Antibodies

The following chemicals were obtained from Sigma, Poole, England: aspirin, apyrase (grade VIII), chlorpromazine, and chloroquine. Mepacrine was obtained from Boots, Nottingham, England, and cocaine was obtained from May and Baker, Dagenham, England. Stypven (Russell viper venom) and prostacyclin (PGI_2) were kindly presented by the Wellcome Foundation (Dartford and Beckenham, England). The antibodies to platelets GPrIb and IIb/IIIa were kindly supplied by Drs B.S. Coller and W. Nichols and the antibodies to vWf were supplied by Dr E.J.W. Bowie. The kit for the platelet factor 4 assay was obtained from Abbott Diagnostics, Wokingham, Berks, England. Cryoprecipitate was obtained from the National Blood Transfusion Service. It was selected to have no red cell agglutinins, warmed to 37°C, passed through a standard filter in the apparatus to remove any particles, and then added to blood warmed to 37°C.

Patients

Twenty patients with severe atherosclerosis were studied seven times in 3 months. The correlations presented are derived from comparisons of the mean value for each individual. (Less complete data on normal subjects were similar).

Sixteen vWd patients were repeatedly examined. They were considered to be types I, IIA, and B, with factor VIIIC, factor VIIIcAg, and RiCof from 0% to 40%. Multimeric analysis was not performed.

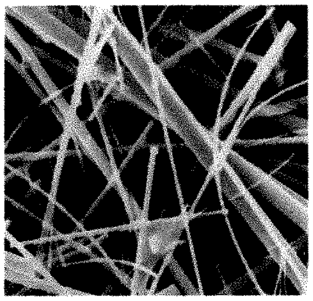

Fig 2. Scanning electronmicrograph of filter (original magnification ×1,800; current magnification ×810).

Statistics

The degree of correlation was measured by the product moment correlation coefficient (r). Reproducibility: the relative variability of samples was compared using Karl Pearson's coefficient of variation (CV).

RESULTS

Reproducibility

Within sample. Four aliquots from each of six people were tested at 40 mmHg. The mean CV of the drop count between 10 to 20 seconds was 9% ± 4%.

Within patient. Twenty patients with atherosclerosis were studied seven times over a 4-month period. The mean CV between these seven samples (10 to 20 seconds) was 20% ± 11%.

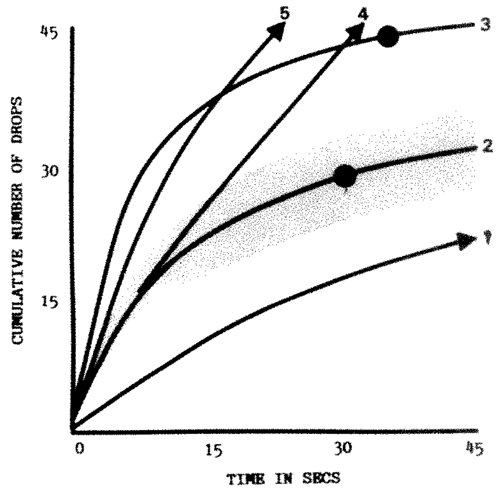

Fig 3. Cumulative drop count plotted against time. (1) Normal heparinized blood at 5 mmHg pressure. (2) Normal heparinized blood at 40 mmHg; shaded area indicates range (1 SD). (3) Normal heparinized PRP at 40 mmHg. (4) EDTA blood at 40 mmHg. (5) von Willebrands' blood. No blockage, (→); Filter "blocked" (●).

Between patients. The CV was established by comparing the mean of seven samples from each of the 20 patients: CV = 23%.

Platelet retention (10 to 20 seconds) figures were closely correlated with drop counts and had similar CVs.

Pressure

The crucial influence of different pressures was investigated first (Fig 3). Aliquots of the same heparinized normal blood were forced through the filter at different pressures. At 40 mmHg, blood initially passed rapidly through (14 ± 2 drops in 5 seconds; n = 40); within 20 seconds, however, marked slowing had occurred and on the average, the filter blocked in 34 ± 12 seconds (n = 40) when 214 × 10^6 ± 62 (n = 40) platelets had been retained.

At 100 mmHg, initially on the average, 16 drops were forced through the filter but the tracing, platelet retention, and blocking were similar to those at 40 mmHg. At 5 mmHg (Fig 3), the initial rate was slow, but little decrease in the rate occurred (drop ratio 62 ± 20) and no blocking occurred in the filter.

Rate of Passage Through Filter

The volume within the filter was estimated by two methods. The filters were filled with water, and the increase in weight was 8 mg. The overall dimensions (9 mm in diameter; 0.26 mm thick) together with the makers' claim that one-half the volume was glass, gave a calculated volume of 8 mm^3. Two milliliters EDTA PRP and vW PRP at 40 mmHg ran through in a continuous stream, and both took 2.1 seconds (n = 6). From this, the mean transit time can be calculated as 8 milliseconds. Normal heparinized PRP blocks the filter in 26 ± 7 seconds (n = 7). Before any platelets cause slowing, the transit time of normal PRP must be similar to that of EDTA or vW PRP. Thus, platelets exposed for 8 milliseconds to these shearing forces aggregate, accumulate, and finally block the filter.

Platelet Aggregation and Filter Blocking

Sections of the filter were prepared for TEM after 2, 8, and 20 seconds of flow, using normal blood or PRP at 5, 40, and 100 mmHg. Blood and PRP from vW patients, which do not block the filter, were also studied. At 40 mmHg, with normal PRP from 3 seconds on, increasing numbers of platelets were seen and the great majority of these had aggregated, with close apposition of the membranes (Fig 4). By 20 seconds, most of the filter was filled with a mass of aggregated platelets and some centering of the granules had occurred. Some filter fibers were surrounded by platelets, but throughout this time period naked fibers were seen with platelets close to them but with no apparent adhesion. Similarly, there was no apparent interaction of the few WBCs retained with the glass fibers or with platelets. Sections of normal blood at 40 mmHg were more complex, with many RBCs present; again, however, similar masses of platelet aggregates were seen.

At 100 mmHg, the findings were essentially similar to those at 40 mmHg. At 5 mmHg, with normal PRP fixed at the same times, far fewer platelets were present than at 40 mmHg. Although there were some sites of close parallel apposition of platelet membranes (aggregation), more free platelets were apparent. Again there was no evidence of active adhesion to the glass fibers. The appearances using vWd PRP at 40 mmHg were similar to those of normal PRP at 5 mmHg: Few platelets were retained and little aggregation was seen (Fig 5).

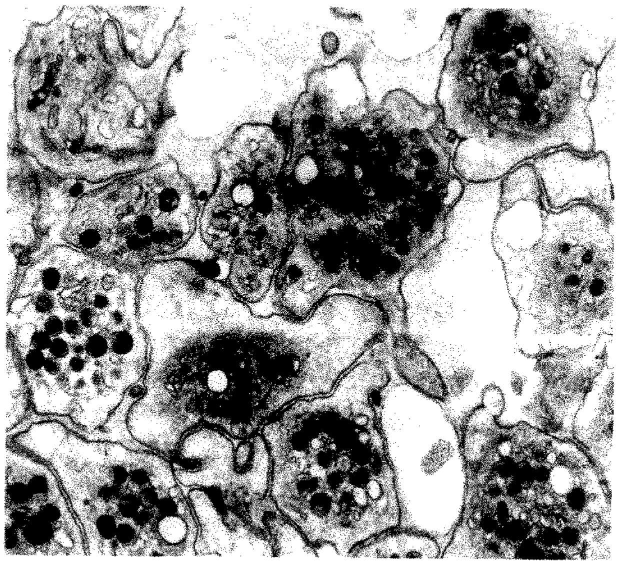

Fig 4. Normal heparinized PRP passed through this filter at 40 mmHg for 8 seconds and fixed within 10 seconds. Many platelets are retained, and already extensive close parallel appositon (aggregation) and early centering of the granules is apparent. Original magnification ×29,160; current magnification ×14,000.

Cellular Damage

Cell damage could lead to leakage of aggregating agents from inside the cells. Effluent normal blood was centrifuged; the degree of hemolysis varied form 0 to, on occasions, 0.25%, but this did not correlate with blockage (n = 20). The plasma platelet factor 4 before passage was 10.6 ng/mL; after passage, the factor 4 was 26 ng/mL (n = 3). This increase would occur if 0.2% of platelets were lysed. The Stypven time of native blood showed little change (35 seconds before and 33 seconds after passage; n = 2). Thus, mechanical damage was minimal.

Calcium and Heparin

An absolute requirement for divalent cations was shown as follows. When native blood was tested at once, blocking occurred in 20 ± 6 seconds (n = 12). Aliquots (2.5-mL) of the same blood collected into citrate (final concentration 0.38%) did not block the filter but ran through in 33 ± 8 seconds (n = 5). Aliquots collected into liquid EDTA (final concentration 0.4%) poured through even faster (22 ± 7 seconds (n = 8)), and few platelets were retained (Fig 3, Table 1).

Blood collected into heparin (final concentration 4.0 IU/mL) blocked the filter in 34 ± 12 seconds (n = 40). Heparin, 20 IU/mL gave similar results.

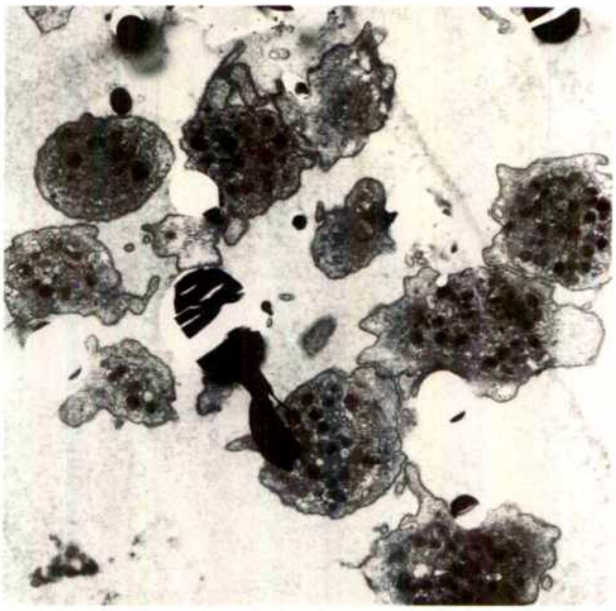

Fig 5. **Heparinized PRP from a patient with vWd was passed at 40 mmHg through the filter for 8 seconds and fixed within 10 seconds. Few platelets were retained. Few areas of close parallel platelet membrane apposition–aggregation are evident. The black objects are transected and shattered glass fibers. Original magnification ×29,160; current magnification ×15,450.**

Effect of RBCs and WBCs

Normal heparinized PRP contained very few RBCs and few WBCs (0.3 to 1.2 × 10^9/L) and, when tested at 40 mmHg, the PRP initially poured through in a continuous stream; slowing (bending in the tracing is shown in Fig 3) was rapid, however, and blocking occurred in 26 ± 7 seconds (n = 7). Even when the pressure was decreased until the initial drop rate of the PRP was similar to that of blood, eg, 14 drops/5 sec, blocking still occurred at 35 ± 5 seconds (n = 3).

WBCs probably do not contribute to filter blocking because PRP with a WBC count of 0.3 to 1.5 × 10^9/L blocked the filter more quickly than did the whole blood with a WBC count of 3 to 10 × 10^9/L. In patients with WBC counts up to 17 × 10^9/L results were normal. WBC retention was initially 45 ± 10% (n = 40) and similar to platelet retention (50% ± 12%), but between 10 and 20 seconds the WBC retention decreased to 22% ± 11% while the platelet retention increased (66% ± 15%).

Table 1. Platelet Retention and Drop Ratio of Normal, vWf, and EDTA Blood at 40 mmHg

Blood Type	n	Retention (%) 0-3 s	Retention (%) 10-20 s	Drop Ratio
Normal hep blood	40	50 ± 12	66 ± 15	35 ± 11
Normal hep blood + cryo	8	78 ± 2	92 ± 2	30 ± 9
vW hep blood	16	28 ± 15	24 ± 16*	53 ± 7
vW hep blood + cryo	8	61 ± 22	83 ± 8	18 ± 5
Normal EDTA blood	8	50 ± 8	13 ± 5*	61 ± 11

vW, von Willebrand's disease; hep blood, blood collected into heparin 4 IU/mL; + cryo, 0.5 mL cryoprecipitate added to 2.0 mL hep blood; EDTA blood, blood collected into 0.4% EDTA

*Filter did not block; others blocked in <40 seconds.

The initial hemoglobin and the WBC count of blood correlated with, and so probably influenced, the initial drop rate ($r = -.35$ and $-.41$, respectively; n = 20), but they had no effect on platelet retention. The percentage of platelets retained in 0 to 3 seconds correlate with the percentage retained between 10 and 20 seconds (r = .82; n = 20). WBC retention 0 to 3 seconds did not, however, correlate with any other parameters; on the other hand, WBC retention (10 to 20 seconds), although low, tightly correlated with the platelet retention (10 to 20 seconds) ($r = .70$; n = 20).

vWf

Neither heparinized nor native blood from 16 patients blocked the filter at 40 mmHg; 2.5 mL blood ran through in 17 ± 7 seconds with little slowing (the drop ratio was 53 ± 7, and platelet and white cell retention was low) (Fig 3, Table 1). Even at 100 mmHg, there was equally little slowing; 2.5 mL ran through in 17 ± 8 seconds (n = 12).

Cryoprecipitate, 0.5 mL, added to 2 mL vWf blood raised the concentration of vWf from 27% ± 8% to 200% ± 6% (n = 5). Normal blocking occurred rapidly, with normal platelet (Table 1) and WBC retention.

Inhibition of Blocking (Table 2)

Inhibition of normal platelet retention and filter blocking was explored (a) by altering the temperature, since most enzymes are temperature-dependent; (b) by altering specific enzyme pathways; (c) by using specific antibodies to cover receptor sites on the platelets; and finally (d) by using nonspecific membrane-active drugs. All inhibitors were added 1 minute before testing.

Temperature. Heparinized blood collected in a room at 37°C and tested at once gave results similar to those obtained with aliquots incubated at room temperature for ≤ 1 hour (37°C: 33 ± 3 drops at 30 seconds; 22°C: 29 ± 4; n = 6).

Aspirin. When added in vitro, aspirin (10 mmol/L final concentration in distilled water) had no significant effect (Table 2). When patients swallowed 300 mg aspirin 2 hours before venepuncture, the filter results were similar to the pre-aspirin tests (n = 3).

Prostacyclin. At high concentration, prostacyclin (dissolved in 50 mmol/L Tris HCl buffer, pH 9.5) had no effect on platelet retention at 0 to 3 seconds, but significantly inhibited platelet but not WBC retention between 10 and 20 seconds. The addition of this buffer alone had no effect.

Apyrase. In the aggregometer, apyrase 1.7 U/mL, dissolved in distilled water abolished aggregation induced by ADP mol^{-4}/L. In the filter, the addition of mol^{-4}/L to heparinized normal blood at 37°C 1 minute before testing decreased the blockage time from 30 to 15 seconds (n = 3). The addition of apyrase before the ADP completely abolished the ADP effect. Thus, the apyrase was fully active. Added to normal heparinized blood, it had no effect on the filter results (n = 6).

Chloroquine. At a final concentration of 0.15 mmol/L this drug, dissolved in distilled water, consistently promoted

Table 2. Platelet and WBC Retention and Drop Ratio in the Presence of Inhibitors

Addition	Concentration	n	Platelet Retention 0-3 s	Platelet Retention 10-20 s	Drop Ratio	WBC Retention 0-3 s	WBC Retention 10-20 s
Chlorpromazine	1.7 mmol/L	4	95	25*	172*	124	63
Cocaine	2.9 mmol/L	7	109	54*	156*	105	64
Chloroquine	1.5 mmol/L	4	108	29*	153*	123	117
Mepacrine	1.0 mmol/L	4	86	26*	157*	131	130
PGI_2	25 ng/mL	5	119	51*	157*	113	127
Aspirin	10 mmol/L	4	—	91	108	—	100
Apyrase	1.7 U/mL	5	125	114	78	88	100

Results are expressed as mean percentage relative to various control results. A low retention figure and a high drop ratio figure indicate inhibition.
*$p < 0.01$

rapid blocking and platelet retention increased from 65% to 91% (n = 3). At a concentration of 0.38 mmol/L, no effect was noted, but at 1.5 mmol/L platelet retention between 10 and 20 seconds was reduced to 30% of the control values and no blocking occurred.

Chlorpromazine, mepacrine, and cocaine. Relatively high concentrations of chlorpromazine, mepacrine, and cocaine dissolved in distilled water produced gross inhibition between 10 and 20 seconds, with results similar to chloroquine 1.5 mmol/L. The effect of lower concentrations was not explored.

Inhibition of WBC retention (Table 2). None of the inhibitors affected WBC retention between 0 and 3 seconds, but on every occasion between 10 and 20 seconds WBC retention was decreased by chlorpromazine and cocaine. Chloroquine, mepacrine, and PGI_2 had no effect.

Effect of antibodies to GPrIb, GPrIIb/IIIa, and vWf (Table 3). Three antibodies to GPrIIb/IIIa were available; one to GPrIb was available. These were reconstituted in distilled water so that 0.1 mL added to 5 mL of normal, heparinized blood gave final concentratoins of 5 to 13 µg/mL. These mixtures were incubated at room temperature for 1 minute. Controls consisted of 5-mL aliquots treated indentically but with no additions. The order of testing was varied. The results expressed as a percentage of the related controls are given in Table 3. All three antibodies to GPrIIb/IIIa halved the platelet retention between 0 and 3 seconds, and two reduced retention 10 to 20 seconds to 20% and 22% of the control values. The third antibody, 7E3, was less active, but with all three antibodies there was little progressive decrease in the drop rate, ie, a high drop ratio. All three also inhibited WBC retention during the period of 0 to 3 and 10 to 20 seconds.

Table 3. Platelet Retention and Drop Ratio in Presence of Antibodies

Antibody Type	n	Platelet Retention 0-3 s	Platelet Retention 10-20 s	Drop Ratio
Antibodies to GPrIIb/IIIa				
10 E5[16]	3	49	22	139
HP1/1D[17]	4	61	20	121
7 E3[16]	2	53	54	111
Antibody to GPrIb				
6 DI[18]	4	105	80	124
Antibody to vWf				
W1-3[19]	5	92	55	145
W1-5[19]	5	68	34	182
93 E 4[19]	5	64	50	154
94 H 5[19]	5	80	53	150

Results are expressed as the mean percentage of the various control values.

The antibody 6DI at a concentration of 2.7 µg/mL completely inhibited ristocetin (1.5 mg/mL)-induced aggregation of normal PRP. Thus, it was fully active. Mixed at a concentration of 13 µg/mL for 1 minute with blood at 20°C, it had at most a minor effect (Table 3).

Four antiboides to vWf were each studied five times. Fifty microliters of antibody added 1 minute before testing to 5 mL normal heparinized blood inhibited blocking and, on average, platelet retention 0 to 3 seconds and 10 to 20 seconds were decreased respectively by 24% and 45% of the controls (Table 3).

DISCUSSION

The main conclusions from these experiments are that the filter is blocked by platelets in two phases. The first, lasting 0 to 3 seconds, requires shear stress, vWf, and GPrIIb/IIIa. The second (10 to 20 seconds) has an absolute requirement for divalent cations. Stress, vWf, and GPrIIb/IIIa are apparently still required.

A global test in which whole blood is forced through capillary-sized holes was deliberately chosen to simulate, in part, the in vivo bleeding time, and it is unlikely to be influenced by a single mechanism. Because Apyrase and aspirin have no significant effect, ADP and thromboxane A_2 are apparently not involved. Cyclic AMP may be (PGI_2), but three phosphodiesterase inhibitors (theophylline, aminophylline, and PGE_1: data not given) had no effect. Heparin and native blood results are similar, thus clotting and a heparin–platelet effect seem unlikely.[20]

This is the first experimental situation that has allowed a precise estimate of the speed of shear-induced platelet aggregation.[21,22] The initial mean transit time with normal PRP, and before aggregates obstruct the flow, is 8 milliseconds, yet in this time platelets are activated and aggregate. Subsequently, the filter is blocked when sufficient platelets have been retained, eg, 70% of platelets in 20 drops (1 mL blood) $\simeq$ 150 × 10^6 platelets.

The contribution of glass that can activate platelets, WBCs, and plasma seems excluded by the reported Nuclepore experiments.[9,10] From the evidence presented, it appears unlikely that WBCs initiate blockage. Chlorpromazine and cocaine inhibit WBC retention and chloroquine and mepacrine do not, but all four agents inhibit platelet retention (Table 2).

Although RBCs have a profound effect on the initial flow rate, their removal in PRP does not impair filter blocking. Thus, ADP leaking from even intact RBCs is irrelevant.

Numerous authors report that platelet retention in glass bead columns[24,25] and in vascular models is abnormal in vWf disease but only in situations of high shear.[26,27] The absence of filter blocking in this model in vWd, its correction by the additon of cryoprecipitate, and the correction by DDAVP[28-30] and the probable effect of high-mol-wt multimers of vWf[3,27] all support the concept that vWf is essential in conditions of high shear.

With use of monoclonal antibodies, it has been shown that GPrIIb/IIIa on the platelet membrane is necessary for filter blockage (Table 3) and that GPrIb is of little or no importance although it may be in other systems.[1,2] In purified systems, GPrIIb/IIIa has been reported to be activated, eg, by thrombin, at a site exposed with a conformational change[31,32] before vWf can bind to the platelet.[33] In these circumstances, however, if fibrinogen is present or added later, the fibrinogen will preferentially bind to the platelet surface or displace the vWf.[34,35] In the filter and in Baumgartner's models, normal fibrinogen levels are present, yet vWf is required. It follows that in stress-induced activation the expression of GPrIIb/IIIa must differ from that which occurs when aggregating agents such as ADP and thrombin are added. In the aggregometer, vWf platelets behave normally after the addition of ADP, and the GPrIIb/IIIa binds to the fibrinogen as the ligand.[16,36] In the high-shear situation, both adhesive proteins, vWf and fibrinogen, may be required,[37] but this does not alter the conclusion that high shear causes a unique expression of GPrIIb/IIIa that requires vWf for platelet aggregation.

The differences in platelet retention between 0 to 3 seconds and 10 to 20 seconds show clearly that two processes are involved, although the events at 0 to 3 seconds (first phase) must also contribute to or even determine the events in the second phase (10 to 20 seconds) since they are closely correlated. There are important differences, however. Table 4 shows that phase 1 requires high shear, vWf together with "available" platelet membrane GPrIIb/IIIa, but is independent of divalent cations (EDTA blood). Phase 2 is presumably also dependent on vWf and GPrIIb/IIIa but differs from phase 1 in that it is inhibited in the absence of divalent cations and by the addition of membrane stabilising drugs.

Table 4. Differences Between Platelet Retention During First Phase (0-3 s) and Second (10-20 s)

Addition	n	Platelet Retention 0-3 s	Platelet Retention 10-20 s
Nil (normal)	40	100	100
vW	16	56	36
Anti-GPrIIb/IIIa	9	54	32
EDTA	8	100	20
Membrane-active drugs	19	100	34
PGI_2	5	119	51

Average differences in platelet retention are expressed as a percentage of the appropriate normal values.

Shear stress initially appears to expose GPrIIb/IIIa in a way that is independent of fibrinogen and divalent cations. This locus with vWf permits platelet aggregation. Thereafter, the same or another vWf molecule becomes attached to GPrIIb/IIIa through a cation-dependent bond, and only this second step is inhibited by perhaps a more general membrane perturbation caused by membrane-active drugs.

The effect of these membrane-active drugs, in admittedly high (mmol/L) concentrations, is not fully understood. The stimulating effect of lower concentrations of chloroquine is typical of some membrane-active drugs. Cocaine and quinine inhibit ADP- and thromobin-induced aggregation.[38] Inhibition by local anesthetics of transmembrane calcium migration[39] and the inhibition of filter blocking by EDTA may be related phenomena. Dibucaine and chlorpromazine are reported to influence membrane phospholipase A2.[40] The inhibitory effect of PGI_2 at 25 ng/mL may be due to a "membrane-stabilizing" effect,[41] and PGI_2 is reported to prevent the binding of vWf to platelet GPrIb.[42] The lack of temperature dependence favors a conformational change rather than an enzyme effect. Finally, it must be pertinent that apyrase, PGE_1 and dibucaine all inhibit the rate of binding of antibody to GPrIIb/IIIa in both buffer- and ADP-stimulated platelets.[31]

In conclusion, we propose, in agreement with Schmid-Schonbein et al[43] that acute rapid bending of the platelet causes membrane perturbation and that this alone can, in milliseconds, induce a unique exposure of GPrIIb/IIIa. Initially, only vWf is required. Seconds later, calcium is required for further platelet aggregation. Collagen, subintima,[44] RBCs,[45] and thrombin are not required for this type of aggregation, nor probably is fibrinogen[46] or ADP. This is the first clear demonstration of a further independent way of inducing platlet aggregation. Accordingly, in patients with vWd, the long bleeding time at 40 mmHg results from an absence of vWf, which is essential for shear-induced platelet aggregation in this system and presumably in other systems. In contrast, ADP and thrombin involve a different expression of GPrIIb/IIIa[34] since aggregation then requires fibrinogen[31,34,37] and vWf is irrelevant. Thus, ADP and thrombin apparently do not play a major part in determining the normal bleeding time. These findings presumably are relevant to hemostasis and thrombosis.

ACKNOWLEDGMENT

We thank Drs M.B. Zucker, B.S. Coller, and P.J. Green for valuable criticism; Drs B.S. Coller, E.J.W. Bowie, and W.L. Nichols for the gifts of antibodies; R. Griffin, FIMLT, for the electronmicroscopy; D. Ling for designing and constructing the device; Pall (Biomedicals), Portsmouth, England, for the filter sheets; S.A. Jamieson for extensive secretarial help; and the Portsmouth surgeons for permission to study the atherosclerotic patients.

von Willebrand Factor Is Present on the Surface of Platelets Stimulated in Plasma by ADP

By Burt Adelman, Patricia Carlson, and Patrick Powers

von Willebrand factor (vWf) can bind to glycoprotein (GP) IIb/IIIa on activated platelets. The significance of this interaction is unclear, however, because it has not been possible to detect vWf binding to GPIIb/IIIa on platelets stimulated in plasma. We have developed an indirect, flow cytometry assay that uses fluorescein-labeled antibodies to detect vWf and fibrinogen on platelets. Using this assay, we found vWf on the surface of platelets stimulated in plasma by ADP. The number of platelets that bound vWf increased in proportion to ADP concentration and incubation time. Washed platelets in a protein-free buffer activated by 1 μmol/L calcium ionophore A23187 or 10 μmol/L ADP also bound vWf, suggesting that we were detecting surface binding of α-granule–derived vWf. Monoclonal antibodies against the vWf binding site on GPIb (6D1) and the vWf and fibrinogen binding sites on GPIIb/IIIa (LJP5 and LJ-CP8, respectively) were used to characterize the mechanism of vWf binding to stimulated platelets. Ristocetin-induced binding of vWf was inhibited by 6D1, and ADP-induced binding of fibrinogen was inhibited by LJ-CP8. None of these antibodies inhibited ADP-induced vWf binding. Aspirin and prostaglandin E_1 also inhibited ADP-induced binding of vWf in platelet-rich plasma. During platelet activation in plasma, vWf derived from α-granules becomes bound to the platelet surface possibly being transferred already associated with a binding site.

PLATELET ADHESION and aggregation are the first hemostatic events to occur following vascular injury. These processes depend on platelet association with the adhesive proteins von Willebrand factor (vWf) and fibrinogen. Although much is known about these initial steps of normal hemostasis, the exact molecular mechanism of platelet plug formation has not yet been defined. In vitro in the presence of ristocetin, von Willebrand factor binds to the platelet membrane glycoprotein Ib (GPIb).[1] Von Willebrand factor binding to GPIb is not energy dependent and will occur even if platelets have been formaldehyde-fixed.[2] In contrast, fibrinogen binding to the GPIIb/IIIa complex is energy dependent and occurs only after platelet activation.[3] The current model of platelet plug formation postulates that vWf–GPIb interaction is a passive process that mediates platelet adhesion to the subendothelium, after which platelet activation results in fibrinogen binding to GPIIb/IIIa and platelet aggregate formation.

Recent studies demonstrated that exogenous vWf can bind to GPIIb/IIIa on washed platelets stimulated by adenosine diphosphate (ADP) or thrombin.[4-11] Although Lombardo et al concluded that vWf and fibrinogen occupy distinct binding sites on GPIIb/IIIa,[6] the physiologic significance of exogenous vWf binding to GPIIb/IIIa has been questioned because it can be blocked by fibrinogen if present at the concentrations found in plasma.[4,5,11] In addition, Schullek et al were unable to detect binding of vWf to ADP-stimulated platelets in platelet-rich plasma (PRP).[10]

Parker and others have demonstrated that α-granule–derived vWf can be detected on the surface of thrombin-stimulated washed platelets and that it is bound to GPIIb/IIIa.[4,6] To date, no investigations have been conducted that could detect the presence of secreted, platelet-derived vWf on the surface of platelets activated in plasma. Because platelet α-granules store vWf and their membranes contain GPIIb/IIIa,[12-14] we considered the possibility that activated platelets might transfer endogenous vWf directly to their surface by binding to α-granule GPIIb/IIIa. To examine this hypothesis, we developed a unique immunofluorescent flow cytometry assay to detect vWf on platelets stimulated in plasma by ADP. Our data suggest that vWf can be detected on the surface of these platelets and that it is derived from secreted α-granule stores.

MATERIALS AND METHODS

Normal human PRP and washed platelets were prepared from sodium-citrate anticoagulated blood as previously described.[15] Monospecific fluorescein-labeled goat anti-human vWf IgG antibody and fluorescein-labeled nonspecific goat IgG were obtained from Atlantic Antibodies (Scarborough, ME). Monospecific fluorescein-labeled goat anti-human fibrinogen IgG antibody ($F(ab')_2$ fragment) was obtained from Cooper Biomedical (Malvern, PA). The monoclonal antibodies LJ-CP8 (Fab fragment) and LJP5 (Fab fragment) were kindly provided by Dr Zaverio M. Ruggeri, Scripps Clinic and Research Foundation, La Jolla, CA. The monoclonal antibody 6D1 was kindly provided by Dr Barry Coller, SUNY, Stony Brook NY.[1,6] Aspirin and prostaglandin E_1 were obtained from Sigma Chemical, St Louis. All other materials were reagent grade or better and were obtained from common suppliers.

Assessment of vWf and fibrinogen binding to platelets in PRP by fluorescent flow cytometry. PRP was incubated at room temperature with 5 μmol/L ADP or 1.5 mg/mL ristocetin. The platelet–agonist mixture was swirled only once during incubation because constant mixing promotes formation of large aggregates, which interfere with subsequent analysis. The reaction was stopped by addition of an equal volume of buffered 2% formaldehyde. The platelets were formaldehyde fixed and washed as previously

described[15] and immunostained with fluorescein-labeled anti-vWf or anti-fibrinogen antibody by incubation at 4°C for 30 minutes. The antibodies were used at saturating concentrations, which were determined by trial and error. After staining, excess antibody was removed by washing the platelets twice by centrifugation (1,200 g for 10 minutes 4°C) in phosphate-buffered saline (PBS) (0.01 mol/L sodium phosphate, 0.15 mol/L NaCl, pH 7.4). After the final wash, the platelets were diluted to ~50,000 per μL in filtered PBS. In some experiments, platelet activation was inhibited by the addition of aspirin and prostaglandin E_1 (final concentrations 2.5 mmol/L aspirin and 3 μmol/L PGE_1) to the PRP prior to ADP stimulation. In these experiments, the platelets were incubated with the inhibitor mixture for 15 minutes at 37°C prior to activation.

We used an Ortho 50H fluorescence flow cytometer equipped with a 2140 data handling computer (Ortho Diagnostics, Westwood, MA) and a 5-W argon-ion laser run at 250 mw power for fluorescence analysis of immunolabeled platelets. Calibration of the fluorescence gain settings was done daily using Fluorotrol GF (provided by Ortho Diagnostics). To prevent inclusion of aggregated platelets or platelet fragments, a sizing gate was set by examination of both right-angle and forward-angle scatter signals from formaldehyde-fixed resting platelets. Approximately 80% of resting platelets were included within this gate. Following activation by ADP or ristocetin, 65% ± 10% (SD) of all platelets were included within this gate. Fluorescence analysis of platelets that fell within the sizing gate was then conducted using log amplification. For each sample, 10,000 platelets were analyzed. Stimulated platelets labeled with anti-vWf or anti-fibrinogen antibody whose fluorescence signal intensity was greater than that of 100% of similarly stained resting platelets were counted as positive for agonist-induced binding of vWf or fibrinogen. Results are reported as percentage of positive platelets. Analysis of the data in this manner sacrifices sensitivity for specificity. By only counting as positive those cells whose fluorescence intensity is greater than 100% of the control cells we ignore all cells whose fluorescence intensity may have shifted to a higher level yet still remain within the control range.

Nonspecific binding of fluorescein-labeled antibody to resting and activated platelets was determined by conducting experiments identical to those described above except that fluorescein-labeled nonspecific goat IgG was substituted for specific antibody. The concentration of nonspecific antibody used was equivalent to that of the specific antibody. Less than 2.0% of all platelets in PRP activated by ristocetin or ADP bound more nonspecific goat IgG than did resting platelets.

Effect of anti-GPIIb/IIIa and anti-GPIb antibodies on vWf and fibrinogen binding to the surface of platelets stimulated in plasma. Monoclonal antibody 6D1 binds to platelet GPIb and blocks ristocetin-induced binding of vWf.[1] The monoclonal antibody LJP5 binds to the vWf binding site on GPIIb/IIIa and blocks ADP-induced binding of exogenous vWf to GPIIb/IIIa and when used as a Fab fragment does not interfere with fibrinogen binding to GPIIb/IIIa.[6] Monoclonal antibody LJ-CP8 also binds to GPIIb/IIIa and blocks binding of both fibrinogen and vWf to GPIIb/IIIa on activated platelets. This antibody was produced and characterized in the same fashion as other anti-GPIIb/IIIa antibodies,[6] (Z.M. Ruggeri, personal communication, March, 1987).

In studies identical to those described above, each antibody was independently added to PRP prior to platelet activation by 5 μmol/L ADP or 1.5 mg/mL ristocetin. The antibody was allowed to incubate with the PRP for 5 minutes prior to platelet activation. In each case, the antibody concentration was adequate to cause total inhibition of binding of fibrinogen or vWf to the targeted membrane receptor, either GPIIb/IIIa (LJP5 and LJ-CP8) or GPIb (6D1). The antibody concentrations used were determined both by trial and error and by review of previously published data.[1,6]

vWf expression on the surface of activated washed platelets. Washed platelets were prepared as previously described[16] and then suspended in TBS (0.01 mol/L Tris, 0.15 mol/L NaCl, pH 7.4) containing 4 mmol/L $CaCl_2$. The washed platelets were activated by addition of 1 μmol/L calcium ionophore A23187 or 10 μmol/L ADP, and the reaction was stopped at various intervals by formaldehyde fixation as described above. The ionophore was prepared as a 100 μmol/L stock solution in dimethyl sulfoxide (DMSO). After fixation, the platelets were immunostained with anti-vWf antibody and analyzed by flow cytometry. In control experiments, DMSO alone was substituted for ionophore.

RESULTS

We were able to detect vWf associated with the platelet surface after activation in PRP. As shown in Fig 1, the number of ADP-stimulated platelets with surface-bound vWf increased during the 5-minute incubation period. The number of platelets with surface-bound vWf also increased in relation to the concentration of ADP added; the peak effect was observed at 2.5 μmol/L ADP (Fig 2). The number of platelets with surface-associated vWf appeared even greater when the PRP was treated with ristocetin. After incubation for 5 minutes, 85% of platelets in PRP stimulated by 1.5 mg/mL ristocetin had surface-bound vWf as compared with 37% of platelets stimulated with 5 μmol/L ADP for the same time period (Fig 1). Mean fluorescence intensity of the entire platelet population also increased after stimulation, and the fluorescence histograms (fluorescence intensity *v* cell number) remained bell-shaped. Thus, platelets that bound vWf were not a unique subset of the entire population. The addition of aspirin and PGE_1 to PRP prior to ADP stimulation significantly reduced the number of stimulated platelets with surface-bound vWf (Table 1).

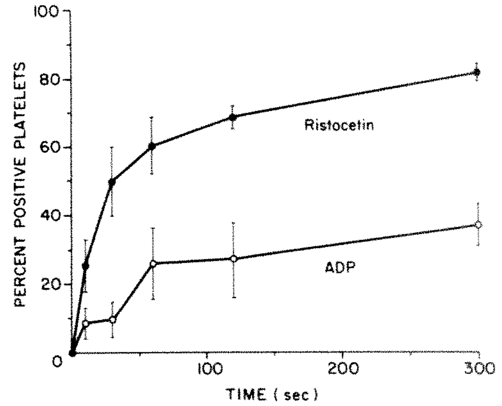

Fig 1. ADP- and ristocetin-induced expression of vWf by platelets in PRP. Five micromolar ADP (final concentration) or 1.5 mg/mL ristocetin was added to PRP. After incubation for the indicated time periods, the reaction was stopped by addition of buffered formaldehyde. Following fixation, the platelets were washed, immunostained with a fluorescein-labeled anti-vWf antibody, and prepared for analysis by fluorescence flow cytometry as described in the Materials and Methods section. Platelets with vWf on their surface were detected by their fluorescent signal and are indicated as the percentage of increase in positive platelets. For ristocetin activation, each point represents the mean (± SE) of separate determinations from four donors; forADP stimulation, each point represents the mean (± SE) of four or five separate determinations from four donors.

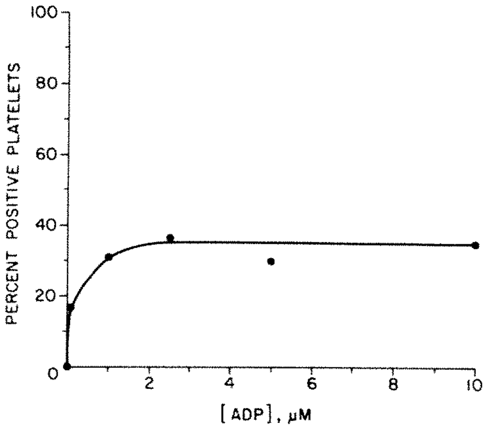

Fig 2. vWf expression on the surface of platelets stimulated by various concentrations of ADP. Platelets in PRP were incubated for 5 minutes with increasing concentrations of ADP (0.1 to 10 μmol/L). After activation, the platelets were prepared for analysis of vWf expression by fluorescent flow cytometry. The increase in percentage of positive platelets indicated a dose-related increase in vWf expression on platelets.

To demonstrate that our observations were not the result of nonspecific binding of fluorescein-labeled anti-vWf antibody to activated platelets, we examined the binding of fluorescein-labeled nonspecific goat IgG to ADP- or ristocetin-stimulated platelets. Platelet binding of nonspecific antibody did not increase with time following stimulation by either agonist and did not exceed the binding of specific antibody by resting platelets (data not shown). From these data, we concluded that our assay system detected the presence of vWf and fibrinogen associated with the platelet surface and not the nonspecific attachment of labeled antibody.

A number of investigators have demonstrated that endogenously secreted vWf can be found on the surface of activated platelets.[5,17-19] We therefore used our assay system to detect vWf derived from α-granules and associated with the platelet surface. Washed platelets in a protein-free buffer were activated by calcium ionophore or ADP. As shown in Fig 3, the number of platelets that expressed surface-bound vWf increased with time following addition of 1 μmol/L ionophore. Five minutes after activation, 50% of the platelets had detectable vWf on their surface. The number of platelets with vWf on their surface that were not ionophore stimulated never exceeded 5% of the total platelet population analyzed. Identical results were obtained when washed platelets were stimulated by ADP.

Table 1. Effect of Inhibition of Platelet Activation on ADP-Induced vWf Binding in PRP*

Incubation Period (s)	Percentage of Inhibition of vWf Binding Following Platelet Activation
10	100%
30	100%
60	89%
120	87%
300	73%

*PRP was incubated with 2.5 mmol/L aspirin and 4 μmol/L PGE$_1$ for 15 minutes at 37°C prior to addition of 5 μmol/L ADP. Each point represents the mean of two or three separate determinations.

Plasma vWf does not effectively compete with fibrinogen for binding to platelets activated in plasma; therefore, we believe that the vWf detected on platelets stimulated by ADP in PRP comes from α-granule stores. In addition, we hypothesize that vWf appears on the platelet surface already bound to an α-granule–derived receptor such as GPIIb/IIIa. To examine this possibility, we conducted a series of blocking experiments using monoclonal antibodies that bind to GPIb and block vWf binding (6D1), or bind to GPIIb/IIIa and block vWf (LJP5) and fibrinogen (LJ-CP8) binding[1,6] (Z.M. Ruggeri, personal communication, March, 1987). We used Fab fragments of LJP5 and LJ-CP8 to minimize nonspecific, stearic blocking effects. If our hypothesis was correct, exogenously added antireceptor antibody would not block vWf expression on ADP-stimulated platelets.

In separate experiments each antibody was added to platelet-rich plasma prior to platelet activation by ADP or ristocetin. Each antibody was used at a concentration that exceeded the minimum necessary to block binding of fibrinogen or vWf to the target membrane protein completely. Adding 6D1 to PRP completely inhibited the effect of ristocetin on expression of vWf but had no effect on vWf binding after platelet stimulation by ADP (Table 2). Fab fragments of the antibody CP8 totally inhibited fibrinogen binding to ADP-stimulated platelets but had no effect on ADP-induced vWf expression. Neither did the Fab fragments of the third antibody, LJP5, have any effect on ADP-induced binding of fibrinogen or vWf.

DISCUSSION

In this study, we demonstrated that vWf appears on the surface of platelets that have been stimulated by ADP in plasma. Although it is well established that vWf can bind to

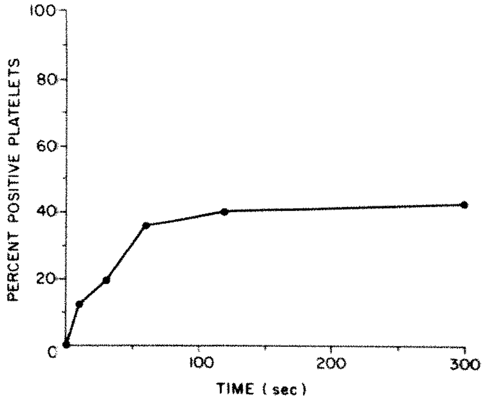

Fig 3. Calcium ionophore A23187-induced expression of vWf on the surface of washed platelets. Washed platelets in a protein-free buffer containing 4 mmol/L CaCl$_2$ were incubated with 1 μmol/L ionophore. At various time intervals, the incubation was stopped by addition of buffered formaldehyde and the platelets were prepared for analysis of vWf expression by fluorescence flow cytometry. Increased vWf expression is indicated by the rise in percentage of positive cells over time. Each point represents the mean of separate determinations from two donors.

Table 2. Effect of Anti-GPIb and Anti-GPIIb/IIIa Antibodies on vWf and Fibrinogen Binding to Platelets Stimulated in Plasma

Antibody* (Concentration)	Percentage of Inhibition of vWf or Fibrinogen Binding Following Platelet Activation		
	ADP		Ristocetin
	vWf (%)	Fibrinogen (%)	vWf (%)
6D1 (20 μg/mL)	0	—	100
LJ-CP8 (65, 130 μg/mL)	0	100	—
LJP5 (0.22, 0.45, 1.3 mg/mL)	0	0	0

Each antibody was added independently to PRP prior to addition of 5 μmol/L ADP or 1.5 mg/mL ristocetin (final concentrations). After incubation for 5 minutes, the platelets were formaldehyde fixed and assayed for vWf or fibrinogen expression as described in the Materials and Methods section. Each point represents the mean of two or three separate determinations.

*6D1 binds to GPIb and blocks vWf binding, LJ-CP8 binds to GPIIb/IIIa and blocks vWf and fibrinogen binding, and LJP5 binds to GPIIb/IIIa but blocks only vWf binding.

the GPIIb/IIIa complex after platelet activation,[4-8] no previous investigation has detected vWf on the surface of platelets activated by ADP in plasma. This is probably because fibrinogen, at the concentration found in blood, can totally block binding of exogenous vWf to GPIIb/IIIa even though there are distinct vWf and fibrinogen binding regions on the GPIIb/IIIa complex.[4-6,11] By using a fluorescein-labeled anti-vWf antibody to probe for platelet-bound vWf, we were able to detect the binding of α-granule–derived vWf to activated platelets. vWf from this source cannot be detected by conventional binding studies, which only follow platelet attachment of exogenously added vWf.

Platelet α-granules contain at least 10% of the total blood content of vWf, and, following platelet activation, secreted vWf is attached to the platelet surface.[4,17-19] Fernandez et al demonstrated that α-granules contain some vWf multimers that are larger than any normally found in plasma and that these molecules readily associate with the platelet membrane after platelet stimulation.[18] To confirm that our assay could detect surface-bound vWf derived from α-granules, we examined washed platelets stimulated by ionophore A23187 or ADP in a protein-free buffer. We found that stimulated washed platelets had vWf on their surface and that the percentage of platelets with surface-bound vWf increased with time. Nonactivated platelets did not demonstrate an increase in surface-associated vWf during the same time period.

We detected increased vWf on the surface of 37% of the ADP-stimulated platelets. This is probably an underestimate of the actual number of stimulated platelets with surface-bound vWf. Because we counted as positive only those cells whose fluorescence intensity was $>100\%$ of control cells, we probably excluded platelets that bound vWf but did not generate a fluorescence signal strong enough to be distinguished from the entire population of resting platelets. Such platelets, following stimulation, may have bound only enough vWf to cause their fluorescence intensity to shift from a lower to higher level within the control range. This possibility is supported by our observation that, following activation, the mean fluorescence intensity of the entire platelet population increased and the fluorescence intensity histogram remained bell-shaped. Setting too narrow a platelet-sizing gate on the flow cytometer may also have contributed to underestimating the number of vWf-positive platelets. Our gate was set to exclude all aggregates and particles smaller than 2 μm in diameter. A larger gate might have included more positive platelets but would have included particles and aggregates that might have introduced artifacts into the data. For the purpose of this study, we believe it appropriate to have used the most rigorous criteria for distinguishing positive from negative cells. Finally, although the conditions under which we conducted our studies, incubation at room temperature without stirring, may not permit optimal platelet release, these conditions were chosen because they match those of previous investigations of ADP-induced platelet attachment of vWf in plasma.[10]

Because plasma vWf cannot effectively compete with fibrinogen for binding sites on ADP-stimulated platelets, we hypothesized that the vWf detected on platelets stimulated in plasma was derived from α-granules and possibly transferred to platelet surface already bound to a membrane receptor. To investigate this hypothesis, we conducted a series of blocking studies using monoclonal antibodies directed against GPIb and GPIIb/IIIa. The antibody 6D1, a well-characterized anti-GPIb antibody,[1] completely blocked vWf binding to ristocetin-stimulated platelets in PRP but had no effect on platelet surface vWf association after ADP stimulation. Fibrinogen binding to ADP-stimulated platelets was blocked by Fab fragments of LJ-CP8, an antibody directed against GPIIb/IIIa that blocks both vWf and fibrinogen binding. Neither LJ-CP8 nor Fab fragments of LJP5, an antibody that specifically blocks vWf binding to GPIIb/IIIa,[6] interfered, however, with the appearance of vWf on the surface of ADP-stimulated platelets. We also demonstrated that inhibition of platelet secretion by incubation of PRP with aspirin and PGE_1 prior to stimulation inhibited ADP-induced binding of vWf.

Taken together, these studies suggest that vWf may be transferred to the platelet surface already bound to a receptor site during ADP activation in plasma. Because it has already been shown that α-granule membrane proteins can be found on the platelet surface following activation,[20] we suspect that this binding site could be the α-granule GPIIb/IIIa. However, our studies did not allow us to determine this specifically. Platelets may also have internal stores of GPIb;[21] but, GPIb has not been shown to be associated with α-granule membranes, and therefore we believe it less likely to be the site of vWf binding following ADP stimulation. vWf binding to an α-granule–derived receptor prior to surface association may explain why Parker et al were unable to achieve total blocking of binding of platelet vWf to thrombin-stimulated platelets activated in buffer containing the anti-GPIIb/IIIa antibody 10E5.[4]

An alternative mechanism for binding of secreted vWf could also exist. α-Granules contain a unique family of very high-mol-wt vWf multimers not present in plasma that have enhanced platelet binding characteristics.[18] These multimers, released into the plasma following platelet activation, may be able to compete effectively with fibrinogen for platelet GPIIb/IIIa binding sites. Our experiments with anti-GPIIb/IIIa and anti-GPIb antibodies suggest that this does not occur on the platelet surface; however, binding may occur within the platelet canalicular system and the blocking antibodies may not gain access to this space.

Our data corroborate those of other researchers indicating that vWf can bind to stimulated platelets and demonstrate that vWf is present in increased amount on the surface of platelets stimulated by ADP in plasma. The findings are consistent with the observation that vWf binds to ADP-stimulated platelets in PRP prepared from individuals with congenital afibrinogenemia.[7,22] In these individuals, vWf binding to GPIIb/IIIa partially substitutes for fibrinogen in supporting platelet aggregate formation. Whether platelet surface association of secreted vWf contributes to platelet aggregate formation or serves to enhance platelet adhesion in normal individuals remains to be determined.

Cytogenetic and Cytochemical Studies on Progenitor Cells of Primary Acquired Sideroblastic Anemia (PASA): Involvement of Multipotent Myeloid Stem Cells in PASA Clone and Mosaicism With Normal Clone

By Tatsuhiko Amenomori, Masao Tomonaga, Itsuro Jinnai, Hisashi Soda, Hiroaki Nonaka, Tatsuki Matsuo, Yoshiharu Yoshida, Kazutaka Kuriyama, Michito Ichimaru, and Tadashi Suematsu

By cytogenetic and cytochemical analyses of individual hematopoietic colonies, we investigated clonality in progenitor compartments of primary acquired sideroblastic anemia (PASA). Two of our four subjects had reduced but countable numbers of CFU-E, BFU-E, and GFU-GM in methylcellulose culture. In one patient with cytogenetic abnormality of 47, XX, +8 in 67% of the bone marrow cells, cytogenetic analysis of individual erythroid bursts and granulocyte/macrophage colonies demonstrated two populations with and without 8 trisomy, the trisomy clone being 38% in BFU-E and 50% in CFU-GM. These findings indicate involvement of multipotent stem cells in PASA clone and mosaicism of two distinct populations in erythroid as well as granulocyte/macrophage progenitor compartments, the abnormal PASA clone and probably the normal clones. In another case with no cytogenetic abnormality, repeated iron staining showed that 31% to 40% of CFU-E and 25% to 54% of BFU-E had erythroblasts with heavy iron deposits. An ultrastructural analysis of 25 individual erythroid bursts revealed that 32% had highly dysplastic erythroblasts with marked ferruginous iron accumulation in the mitochondria. The other 68% and 15 normal bursts from a healthy control did not have noticeable dysplastic changes and iron deposits in the mitochondria. This cytochemical/ultrastructural mosaicism seems to be compatible with the cytogenetic mosaicism. However, whether the BFU-E derived from abnormal PASA clone selectively manifest iron accumulation in the mitochondria or whether the PASA clone itself shows variable degrees of abnormal iron metabolism remains to be determined by simultaneous performance of ultrastructural and cytogenetic analysis for single bursts.

PRIMARY ACQUIRED sideroblastic anemia (PASA) is defined as refractory anemia with cellular bone marrow with erythroid hyperplasia and increased number of ringed sideroblasts. These cells have been considered pathognomonic of this disease since the early descriptions by Bjorkman,[1] Dacie et al[2] and Heilmeyer.[3] Ultrastructural studies established that an accumulation of iron in the mitochondria gives rise to the ring-form deposits,[4,5] and in some cases enzymatic analysis disclosed abnormalities of the heme synthetic pathway inside the mitochondria, such as reduced δ-aminolevurinic acid synthetase (ALA-S) activity.[6,7] It has long been known that some PASA patients later develop acute leukemia,[2,8-10] indicating the preleukemic nature of PASA. Cytogenetic studies have revealed that the abnormal hematopoiesis of PASA is a clonal disorder, as in other myelodysplastic syndromes.[11-15] Prchal et al recently analyzed G6PD isozymes of each cell lineage of mature blood cells, including lymphocytes from a female patient heterozygous for the G6PD locus, and showed that the PASA clone originates in a pluripotent stem cell.[16]

The blood picture of PASA is usually characterized by dimorphism of RBC morphology, which means mosaicism of hypochromic and normochromic cells.[2,10,17,18] It is also easy to find mosaicism of erythroblasts with and without ring-form iron deposits in the bone marrow. The pathophysiologic significance of these findings is not yet known. To investigate clonality in progenitor compartments, we performed cytogenetic analysis of individual hematopoietic colonies obtained from a patient with abnormal karyotype in the bone marrow cells. We also analyzed iron accumulation in single erythroid colonies obtained from another patient, using cytochemical and ultrastructural methods. We found evidence for involvement of multipotent stem cells in PASA clone and for clonal mosaicism with normal progenitor cells.

MATERIALS AND METHODS

Patients

Three patients (cases 1, 2, and 3), whose hematologic findings fulfilled the French-American-British (FAB) criteria for PASA (refractory anemia with ringed sideroblasts),[19] and one patient (case 4) with less prominent ringed sideroblasts were studied. The hematologic data for these patients at the time of the first colony assay are summarized in Table 1. None of these patients had a family history of sideroblastic anemia or underlying hematologic or nonhematologic disease. Cases 1, 2, and 3 showed a slight to moderate degrees of morphological dysplastic changes[19] in erythroid and granulocytic lineages. Case 4 manifested severe dysplastic changes in all cell lineages, including megakaryocytes. All cases had high serum iron levels (256 to 298 μg/dL) and high transferrin saturation (92% to 95%). Bone marrow samples were obtained from the sternum from each patient and one healthy control with informed consent.

Colony Assay

Erythroid colony assay (BFU-E and CFU-E). The method of Iscove et al was used.[20] 2 × 10^5 bone marrow buffy coat cells were

*Percentages among 100 erythroblasts.

plated in a 35-mm Falcon plastic dish containing 1.0 mL of α-medium with final concentrations of 0.88% methylcellulose, 30% fetal calf serum (FCS), 1% deionized bovine serum albumin (BSA) (GIBCO, Grand Island, NY), and 1.0 U/mL erythropoietin (Ep, Step III, Connaught Labs Toronto, Canada). For testing the response to various doses of Ep by BFU-E from the bone marrow in case 2, EP was added to give final concentrations of 0, 0.1, 0.25, 0.5, 1.0, 1.5, and 2.0 U/mL. The plates were incubated at 37 °C in a humidified atmosphere of 5% CO_2 in air. CFU-E were counted on day 7, and BFU-E were counted on day 14.

Granulocyte/macrophage colony assay (CFU-GM). The method of Iscove et al was used with some modification.[21] In brief, 1 × 10^5 light density (1.077/cm^3) mononuclear cells separated from bone marrow specimen, were plated in a 35-mm Falcon plastic dish containing 1.0 mL of α-medium with 0.88% methylcellulose, 20% FCS, and 10% giant-tumor cell-conditioned medium (GIBCO). After 8 days of incubation at 37 °C in a humidified atmosphere of 5% CO_2 in air, cell aggregates with >20 cells were counted as CFU-GM.

Cytogenetic Investigation

Bone marrow cells were directly processed for chromosomal preparation, and cytogenetic analyses were peformed using the standard method and/or the G-banding method.[22]

Chromosome analysis from individual colonies was performed using our own procedure described elsewhere.[23] In brief, individual colonies were aspirated by a finely drawn-out capillary tube, and transferred into a droplet (10 μL) of 0.075 mol/L KCl solution placed on a poly-L-Lysine (Sigma Chemical, St Louis) coated slide. After thorough mixing, the slide was turned upside down to let the droplet hang downward and allowed to stand at 37°C in a wet-chamber for 20 minutes to obtain maximal hypotonic effects. The slide was then turned again, the droplet being upward, and allowed to stand for 15 minutes to let the cells attach to the slide. The fixation process consisted of three steps: First, a small amount (10 μL) of 30% fixative (3:1 methanol:acetic acid) diluted with 0.075 mol/L KCl was added (5 minutes); second, three droplets of 20% ethanol diluted with 0.075 mol/L KCl were added using a Pasteur pipette and allowed to stand for 10 minutes; third, the entire slide was immersed in fresh 100% fixative and allowed to stand for >10 minutes. The slide was flame-dried and stained with Giemsa and/or Q-banded.

Cytochemical Investigation

Perls' reaction for iron[24] was used on air-dried smears of bone marrow cells and Cytospin (Shandon Southern Products, Cheshire, England) smears of single CFU-E and BFU-E. Cytospin-smears were made by aspirating each colony or burst using a finely-drawn-out capillary tube and mixing it with 10 μL of α-medium on a slide glass. The slide was cytocentrifuged at 1,200 rpm for three minutes. Blue granules or deposits were considered accumulated iron in the cytoplasm. Erythroblasts with iron granules arranged along more than one-third of the nuclear outline were defined as ring-form.

Ultrastructural Investigation

For TEM analysis of single BFU-E in case 2 and of one healthy control, 0.5 mL 2.0% glutaraldehyde in 0.1 mol/L phosphate buffer was gently added to dishes for erythroid colonies on day 14. Each erythroid burst became dark and hard after 20 minutes. This made easier aspiration of single bursts using finely-drawn-out capillary tubes. Each burst was transferred into 0.5 mL of 0.1 M phosphate buffer in a multiwell glass plate. Three changes of the buffer were made, and 0.2 mL of 2% OsO_4 was added. After 15 minutes, three changes of the buffer were repeated. Single bursts were then dehydrated in six grades of ethanol from 30% to 100% (10 minutes each). Embedding of each burst in Epon was done by standard method[25] under a dissecting microscope. Ultrathin sections were made on a LKB 4800 (LKB, Bromma, Sweden). The double-counterstain with uranyl acetate and lead citrate was used, and TEM observation followed on a JEM-100B(JEOL, Tokyo). To confirm that high-electron-dense deposits in the mitochondria of the erythroblasts were actually iron accumulation, X-ray microprobe analysis was done using a JEM-100CX (JEOL).

RESULTS

BFU-E, CFU-E, and CFU-GM Enumeration

Numbers of CFU-E and BFU-E were relatively high (though far below normal) in cases 1 and 2 (Table 1). A few degenerative CFU-E and no BFU-E were formed in case 3. No cellular aggregations were present in case 4. Spontaneous erythroid colony formation was absent in all cases when Ep was not added. CFU-GM formed fairly well in all cases, but in reduced numbers.

Cytogenetic Analysis of Bone Marrow Cells and Individual Hematopoietic Colonies in Case 1

The bone marrow direct method revealed that nine (33.0%) of 27 metaphases were aneuploidy of 47, XX, +8, and 18 (67.0%) normal karyotypes. Cytogenetic analysis of individual erythroid bursts and granulocyte/macrophage colonies demonstrated the same mosaic condition in both BFU-E and CFU-GM compartments (Table 2). In a few individual bursts and GM-colonies, two or more metaphases could be analyzed. They all showed either normal or abnormal karyotype.

Table 2. Cytogenetic Analysis of Individual Colonies in Case 1

Colony Type	No. of Colonies (Metaphase) Examined	Colony With 46,XX		Colony With 47,XX, +8	
		n (%)	No. of Normal Metaphases/ No. of Metaphases Examined	n (%)	No. of Abnormal Metaphases/ No. of Metaphases Examined

*Only colonies with coarse iron granules (Fe$^+$) in the cytoplasm of colony-composing erythroblasts were regarded as abnormal.

†Only one normal BFU-E showed ferruginous iron accumulation in a few mitochondria of two erythroblasts among ~300 burst-composing cells.

Cytochemical Analysis of Single Erythroid Colonies and Bursts in Case 2

The results of serial cytochemical investigations on the iron deposits in individual erythroid colonies and bursts from case 2 are shown in Table 3. In the first analysis, ~30% of bursts were iron deposit positive. In some bursts, all the erythroblasts had heavy deposits of iron, but in others only a part (30% to 60%) of the erythroblasts had detectable amounts of such deposits. In some erythroblasts, iron granules were in ring-form like the ringed sideroblasts of the bone marrow smears, but in others they were scattered in the cytoplasm, making it difficult to consider them equivalent to ringed sideroblasts (Fig 1). Ultrastructural study was therefore needed to find the actual site of iron accumulation. In the second and third analyses, iron-positive and iron-negative populations were observed in both CFU-E and BFU-E compartments.

Ultrastructural Analysis of Single Erythroid Bursts in Case 2

The bursts could be classified into two distinct populations, one with ferruginous iron deposits inside the mitochondria (Fig 2A and B), which we called Fe-positive, and the other completely without iron deposits in the mitochondria (Fig 3), which we called Fe-negative. In the Fe-positive population, there were few iron deposits outside the mitochondria; only occasional ferritin clusters were seen (Fig 2B), suggesting that the scattered pattern of iron deposits observed in the cytochemical preparations of single colonies or bursts indicates that most of the iron has actually accumulated in the mitochondria. The percentage of Fe-positive bursts identified cytochemically, including both ring-forms and scattered-forms, was close to that identified by TEM (Table 3). X-ray microprobe analysis confirmed that the electron-dense deposits in the mitochondria were indeed ferruginous.

In each Fe-positive burst, almost all erythroblasts had slight (containing thin iron deposit layer along cristae) to extensive (containing heavy iron deposit filling the space between cristae) iron accumulation in almost all visible

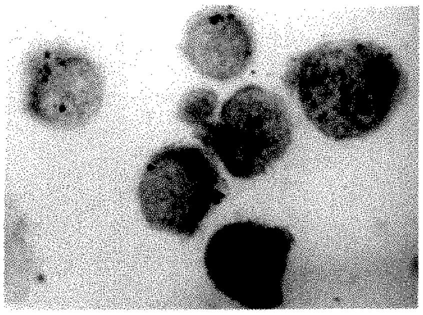

Fig 1. Cytospin-smear of an erythroid burst from case 2 stained for iron (Perls' reaction). The coarse, blue iron granules are scattered in the cytoplasm. Only a few erythroblasts in this burst show ring-form iron deposits. (Original magnification ×1,000; current magnification ×500.)

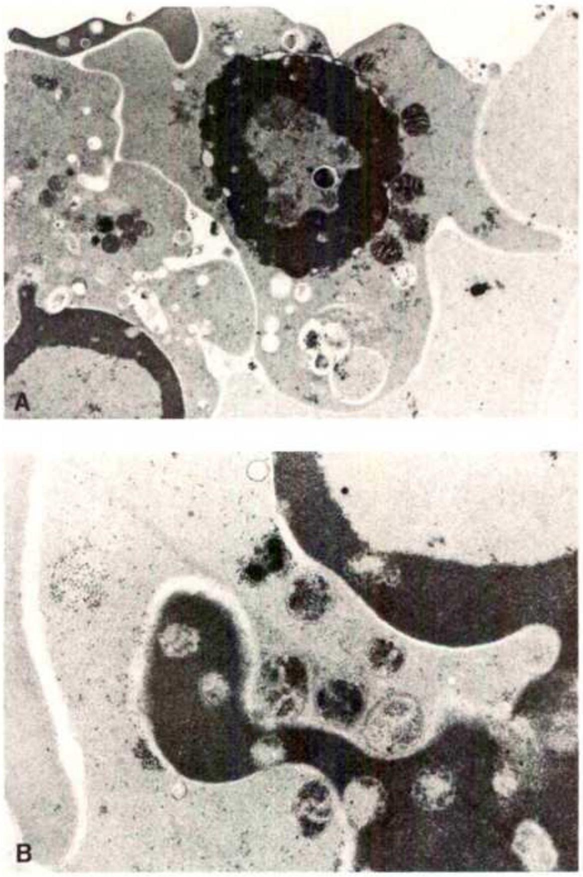

Fig 2. TEM of a day-14 erythroid burst from case 2, with heavy iron deposits. (A) The erythroblasts show marked dysplastic changes, as well as typical ring-form iron deposits. There is marked disintegration of the chromatin structure, disappearance of the nuclear envelope, scanty or almost no ribosomes, vacuoles in the cytoplasm and in the nucleus, and severe degeneration of the mitochondria (vacuolation and disruption). (Original magnification ×5,000; current magnification ×2,500). (B) In some erythroblasts, a few ferritin clusters are seen outside the mitochondria. The ribosomes are visible but few, with no polyribosome formation, suggesting that there are multiple background disorders in the cellular biochemistry of PASA erythroblasts (Original magnification ×13,000; current magnification ×6,500).

mitochondria, indicating that TEM analysis was more sensitive than light-microscopic cytochemistry for the detection of iron deposits in the cytoplasm. At the same time, severe dysplastic changes were observed. In contrast, in bursts with only Fe-negative erythroblasts, the cells had almost normal ultrastructural appearance without any dysplastic changes. Fourteen of 15 bursts from a normal control had Fe-negative erythroblasts, and all cells seemed ultrastructurally normal (Fig 4A). In one burst, however, a few erythroblasts had thin iron deposits in mitochondria (Fig 4B).

Erythropoietin Sensitivity of Erythroid Progenitors in Case 2

As shown in Table 4, the numbers of total CFU-E and Fe-positive CFU-E increased proportionately to increasing doses of Ep and reached a plateau at 1.0 U/mL. Thus, there

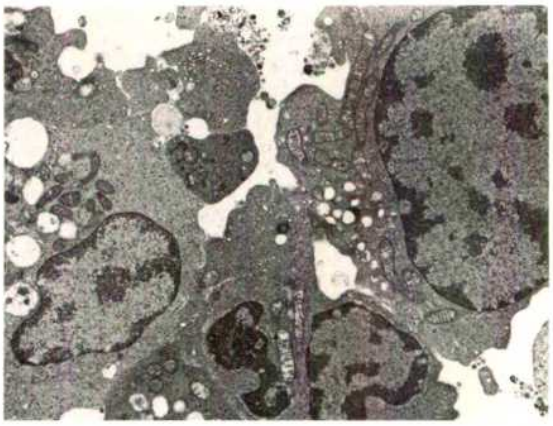

Fig 3. TEM of a day-14 burst from case 2, with normal appearance. The erythroblasts show almost normal ultrastructural morphology; there are abundant polyribosomes and mitochondria with no iron accumulation (Original magnification ×5,500; current magnification ×2,750).

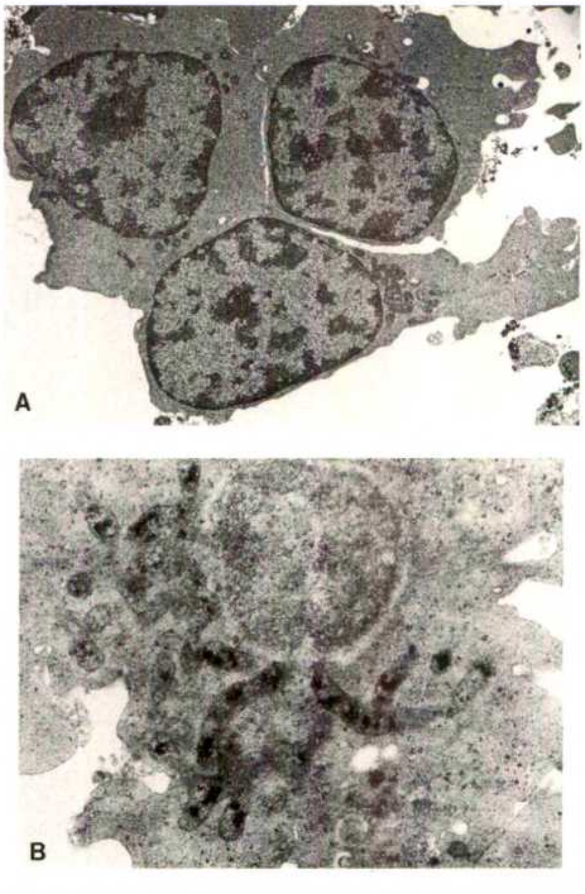

Fig 4. TEM of a day-14 burst from a normal control. (A) The erythroblasts show entirely normal appearance with no karyorrhexis and no abnormal iron deposits in the cytoplasm or in the mitochondria. (B) In one burst in 15, a few erythroblasts among some 300 cells observed had iron deposits in the mitochondria.

Table 4. Erythropoietin-Dose Response of Erythroid Progenitors (Case 2)

Erythropoietin Dose (U/mL)	CFU-E No. 2 × 10^5 Cells Total	CFU-E No. 2 × 10^5 Cells Fe$^+$ (%)	BFU-E No. 2 × 10^5 Cells Total	BFU-E No. 2 × 10^5 Cells Fe$^+$ (%)	
0.1	12.6 ± 0.6	3.3 ± 1.5 (26.2)	3.7 ± 1.2	3.0 ± 1.0 (81.0)	
0.5	32.7 ± 1.5	6.0 ± 1.7 (18.3)	16.0 ± 1.7	5.7 ± 0.5 (35.6)	1
1.0	36.3 ± 1.5	12.3 ± 1.2 (33.9)	17.3 ± 1.5	10.3 ± 1.5 (59.5)	2
1.5	34.3 ± 1.5	11.7 ± 2.0 (34.1)	20.6 ± 1.5	11.3 ± 1.5 (54.8)	3
2.0	34.7 ± 1.4	12.3 ± 2.5 (35.4)	32.3 ± 1.5	18.3 ± 0.5 (56.6)	4

Numbers of CFU-E and BFU-E are the mean ± 1 SD of triplicate culture. All CFU-E and BFU-E enumerated were aspirated individually and stained for iron. The percentage of Fe$^+$ BFU-E at erythropoietin 0.1 U/mL was compared with those at higher doses using Fisher's exact test. (1, $P = .0065$; 2, $P = .1478$, 3, $P = .0867$; 4, $P = .0970$).

was no difference in Ep sensitivity between Fe-positive and Fe-negative CFU-E compartments. In contrast, Fe-positive BFU-E seemed to be more sensitive to Ep since Fe-positive BFU-E grew predominantly at 0.1 U/mL. The difference in percentage of Fe-positive BFU-E was statistically significant, however, only between 0.1 and 0.5 U/mL.

DISCUSSION

The present cytogenetic study on individual hematopoietic colonies revealed in case 1 the presence of an identical aneuploid clone in two different cell lineages, providing evidence that the abnormal clone of PASA involves multipotent hematopoietic stem cells. This cytogenetic finding is compatible with the observation by Prchal et al using G6PD isozyme analysis.[16] Their conclusion was that all blood formed elements, including lymphocytes, are derived from the abnormal PASA clone that originated in a pluripotent stem cell. Our study further revealed karyotypic mosaicism in erythroid as well as granulocyte/macrophage progenitor cell compartments. Mosaicism was also present in the direct bone marrow sample. Many cytogenetic studies on PASA bone marrows also disclosed mosaicism.[11-15] Because Prchal et al did not analyze hematopoietic colonies enzymatically, it is not clear whether there was a heterogeneous composition in progenitor compartments in their case. The discrepancy between our results and Prchal's may in part reflect the different stages of PASA at which clonal study was performed. In our series, cases 1 and 2 showed a progressive declining of erythroid burst formation (data not shown), suggesting expansion of the PASA clone.

We obtained higher percentages of population with normal karyotype in erythroid and GM progenitor compartments than in the direct bone marrow sample. It appears possible in vitro to obtain colonies of which progenitor cells belong to normal clones but are inhibited in vivo and unable to deliver normal mature progeny. A similar situation was recently observed in some patients with chronic myeloid leukemia by Dube et al.[26] Our observation in case 2 that Fe-positive BFU-E seemed to have hypersensitivity to Ep may provide, if confirmed in other cases of PASA, a clue to elucidating the underlying mechanism of growth advantage by the PASA clone over normal clone. However, this does not necessarily explain the growth advantage in the multipotent stem cell compartment.

Demonstration of the normal clones remaining in PASA bone marrow as a minor population is important from a therapeutic viewpoint. Theoretically, chemotherapeutic or differentiation-induction regimens such as continuous low-dose cytosine arabinoside (LDAC) regimen may reverse the bone marrow with dominance of PASA clone to remission state. With the LDAC regimen, hematologic remission has been reported to be induced in some patients with PASA.[27,28] However, clonal alternation was not confirmed in these cases.

By combining clonal culture with cytochemical/ultrastructural methods, the present study disclosed in case 2 that Fe-positive and Fe-negative populations are present in the erythroid progenitor compartment of PASA bone marrow. Differences in ultrastructural morphology of erythroblasts in individual bursts were distinct between the two populations. Marked dysplastic changes were observed only in the erythroblasts of Fe-positive bursts, suggesting premature degradation of cells in vitro, which may lead to reduced number of erythroid bursts. This cytochemical/ultrastructural mosaicism in case 2 seems to be compatible with the cytogenetic mosaicism in case 1, Fe-positive bursts being derived from the PASA clone and Fe-negative bursts being derived from the normal clone. If this assumption is correct, one can explain the dimorphism of RBCs in PASA as expression of the clonal mosaicism in this disease. Because a few Fe-positive erythroblasts were observed in one BFU-E from normal control, there still remains a possibility that the mitochondrial iron deposit is not a clonal marker and that the PASA clone itself shows much diversity in degree of defective heme synthesis and produces maturing erythroblasts and RBCs with variable degrees of iron deposits and hemoglobin concentration, respectively.

Several reports describe the relationship between PASA clone and abnormal heme synthesis. Using biochemical methods, Ibrahim et al compared the ALA-S activity and C^{14}-ALA incorporation into heme of erythroblasts directly sampled from PASA bone marrow and of erythroid colonies obtained by culturing the same bone marrow; they found reduced ALA-S activity and C^{14} incorporation in the former but almost normal values in the latter[29,30] and postulated that these erythroid progenitors, biochemically normal in appearance, were derived from residual normal stem cells. Hutcheson et al did an ultrastructural study on erythroid bursts from PASA patients and demonstrated for the first time in vitro distinct iron accumulation in the mitochondria;[31] however, they processed groups of bursts for TEM study instead of analyzing them individually and did not observe bursts of normal appearance.

Mizoguchi et al undertook a light-microscopic/cytochemical investigation of CFU-E and BFU-E from PASA patients,[32] as we did. In one case, they found that all BFU-E were Fe-positive but contained two types of erythroblasts, with and without iron deposits, whereas all CFU-E were Fe-negative. They postulated that BFU-E of the PASA clone can give rise to both types of progenies and Fe-negative CFU-E are those PASA progenies with higher proliferative potential in vitro. Differences in technical sensitivity to iron detection (light-microscopic *v* ultrastructural methods) may account in part for the discrepancy between their work and ours. To establish the significance of ringed sideroblasts in the pathogenesis of PASA, one must perform cytogenetic or G6PD-isoenzyme anlaysis and ultrastructural observation simultaneously for single erythroid bursts.

ACKNOWLEDGMENT

We thank Drs K. Ebata, R. Nonno, and Y. Shimokawa, University of Kurume, for referring their patient to this study.

Phorbol Esters Sensitize Platelets to Activation by Physiological Agonists

By Wolfgang Siess and Eduardo G. Lapetina

Phorbol esters such as phorbol 12, 13-dibutyrate (PdBu; 40 to 200 nmol/L) or 12-*O*-tetradecanoyl phorbol 13-acetate (20 to 80 nmol/L) added to aspirinized platelet-rich plasma (PRP) 5 to 15 seconds prior to various platelet stimuli (epinephrine, ADP, prostaglandin endoperoxide analog U44069, collagen, PAF, or vasopressin) potentiate the rate and extent of aggregation and ATP secretion induced by those agonists. Platelet aggregation, but not secretion, is potentiated at low concentrations of agonists; platelet secretion is potentiated at higher concentrations of the platelet stimuli. Potentiation of platelet responses was also observed when the preincubation time with PdBu was extended to 12 minutes and also occurred in washed platelets. The potentiating effect of phorbol esters is not mediated by formation of arachidonate metabolites or by released ADP. The sensitizing effect of PdBu on platelet aggregation induced by epinephrine is unique, since in contrast to the other platelet stimuli it is also found at maximal concentrations of epinephrine and does not diminish with prolonged preincubation of platelets with PdBu. Activation of protein kinase C ranges from 20% to 80% over control after 1 to 10 minutes of platelet pretreatment with PdBu but dramatically increases after subsequent addition of a stimulus such as vasopressin. In contrast, agonist-induced myosin light chain phosphorylation is reduced after platelet pretreatment with PdBu. The results indicate that protein kinase C activation enhances platelet aggregation and dense granule secretion triggered by physiologic stimuli, although it desensitizes agonist-induced myosin light chain phosphorylation.
© 1987 by Grune & Stratton, Inc.

TWO FUNCTIONS of protein kinase C for platelet activation have been suggested: (a) synergism with Ca^{2+} to induce platelet aggregation and secretion,[1,2] and (b) desensitization of platelet responses to receptor-activating platelet stimuli.[3-12]

Bioactive diacylglycerols or phorbol esters induce either no platelet response or only a small, delayed aggregation and secretion response at concentrations that fully activate protein kinase C. They will, however, evoke rapid, full secretion and aggregation if added together with subthreshold concentrations of Ca^{2+} ionophores.[1,2] Preincubation of platelets with phorbol ester or bioactive diacylglycerols for 1 to 9 minutes causes an inhibition of phospholipase C-induced inositol phospholipid hydrolysis, Ca^{2+} mobilization, thromboxane B_2 (TXB_2) formation, shape change, granule secretion and aggregation induced by various physiological stimuli such as thrombin, vasopressin, PAF or ADP.[4-12] Although 12-*O*-tetradecanoyl phorbol 13-acetate (TPA) added up to 1 minute before thrombin accelerates thrombin-induced dense granule secretion, phosphatidic acid formation, and breakdown of phosphatidylinositol 4,5-bisphosphate of washed platelets incubated at 23°C,[5] most studies have reported and stressed the desensitizing effect of protein kinase C activation on agonist-induced platelet responses. Recent studies have not clarified the situation. On one hand, by incubating platelets for only a short time with TPA (10 seconds before the stimulus), a clear inhibition of thrombin- or ADP-induced shape change, Ca^{2+} mobilization and myosin association with the cytoskeleton was found.[9] Preincubation of platelets with TPA for 1 to 5 minutes before the agonist has also been reported to inhibit shape change, aggregation and ATP-secretion in response to thrombin, PAF, ADP, or U46619 in the presence of extracellular Ca^{2+},[10,11] but it induces a potentiation of ATP secretion in the absence of extracellular Ca^{2+} (<100 nmol/L).[10] On the other hand, other investigators found only a small reduction of agonist-stimulated serotonin release and no inhibition of cytosolic Ca^{2+} increase, myosin light chain phosphorylation, or cytoskeletal assembly after preincubating platelets with TPA for 2 minutes in the presence of extracellular Ca^{2+} (0.05 mmol/L).[12] When TPA was added 20 seconds before a secondary challenge with arachidonic acid or thrombin, an enhanced rate of secretion was observed.[12] Another group found that preincubation (10 seconds to 2 minutes) of platelets with TPA caused a potentiation of serotonin secretion induced by thrombin or U46619 but an inhibition of arachidonate release, TXB_2-formation, Ca^{2+} mobilization, and α-granule secretion.[13] The situation was further complicated if 1-oleoyl,2-acetylglycerol (OAG) was used, since the effects observed were different from those caused by phorbol ester: If added 10 seconds to 5 minutes before or 10 to 60 seconds after thrombin, OAG potentiated thrombin-induced aggregation and serotonin secretion without affecting the Ca^{2+} mobilization.[14]

A clear picture of the role of protein kinase C activation for platelet responses triggered by physiologic agonists has not emerged from these studies. Because all studies (except part of one study, ref. 13) were done using washed platelets, and the washing procedure and type of resuspension buffer may have introduced problems of nonphysiologic platelet behavior, we decided (a) to investigate the effect of phorbol ester on agonist-induced platelet activation in PRP, and (b) to find a method of preparing washed platelets that gave results similar to those obtained in PRP.

MATERIALS AND METHODS

Materials. 4α-Phorbol, 4α-phorbol 12, 13-didecanoate (4α-PDD), phorbol 12, 13-dibutyrate (PdBu), TPA [identical to phorbol 12-myristate, 13-acetate, (PMA)], and prostaglandin E_1 were pur-

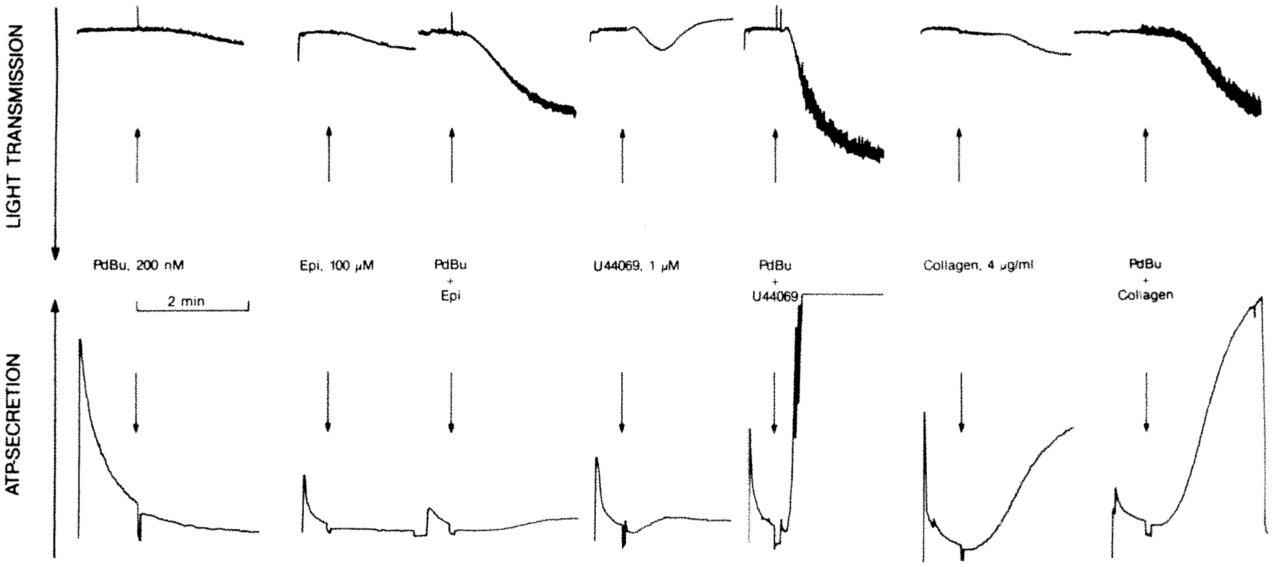

Fig 1. Tracings of aggregation and ATP secretion of aspirinized PRP stimulated by various agonists in the presence or absence of PdBu. PdBu was added simultaneously with the agonists.

chased from Sigma (St Louis). All other substances were obtained as previously described.[15-17]

PRP. PRP was prepared by centrifugation (200 g for 20 minutes) from 120 mL freshly drawn human blood anticoagulated with $^1/_{10}$ vol trisodium citrate (3.8%). PRP was incubated with 1 mmol/L acetylsalicylic acid (aspirin; dissolved as 1 mol/L solution in ethanol) for 15 minutes at 37°C in most experiments and then capped and stored at room temperature. To exclude direct influence of aspirin in plasma on the results obtained, in some experiments (results shown in Figs 1-9) platelets were pelleted by centrifugation (800 g for 10 minutes) after addition of PGI_2 (20 ng/mL) and resuspended in autologous platelet-poor plasma (PPP) containing creatine phosphate (CP) (1 mmol/L) and creatine phosphokinase (CPK) (10 U/mL).

Washed platelets. In studies using washed platelets, PRP—after aspirinization and addition of PGI_2 (20 ng/mL)—was centrifuged, washed once with 10 mL buffer A (20 mmol/L HEPES, 138 mmol/L NaCl, 2.9 mmol/L KCl, 3.3 mmol/L NaH_2PO_4, 1 mmol/L $MgCl_2$, 1 mmol/L EGTA, pH 7.4) containing apyrase (0.6 U/mL

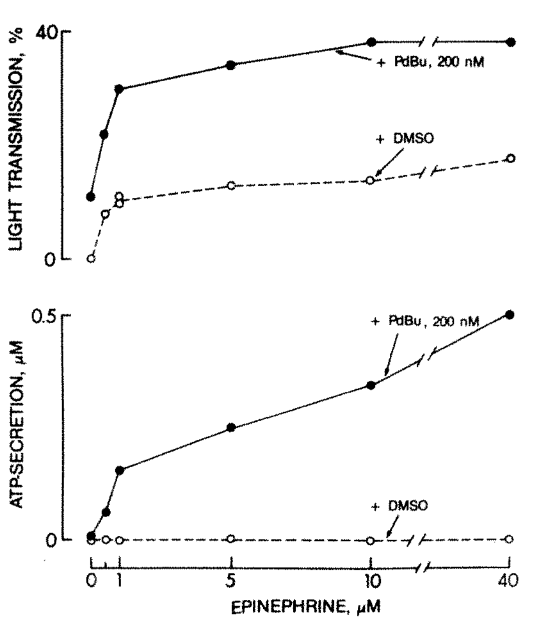

Fig 2. Potentiation of epinephrine-induced platelet responses by PdBu. PdBu (100 nmol/L) or DMSO was added 5 seconds before epinephrine to aspirinized PRP containing CP (1 mmol/L), CPK (10 U/mL). Aggregation and ATP secretion were measured 2 minutes after addition of the agonist. The samples containing DMSO gave results identical to samples without DMSO.

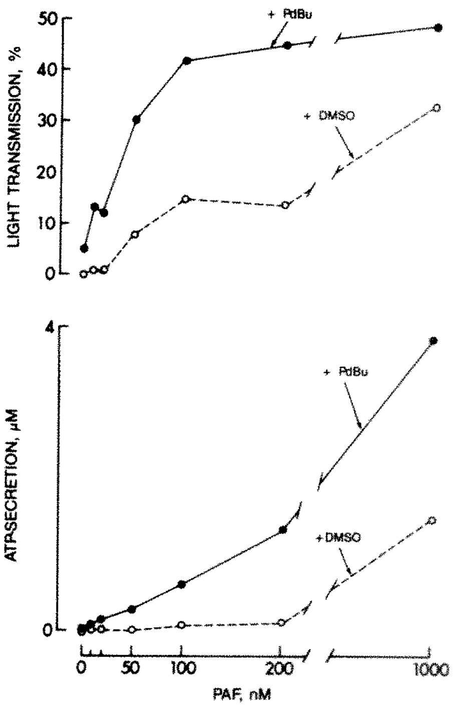

Fig 6. Potentiation of PAF-induced platelet responses by PdBu (200 nmol/L). Conditions were the same as those described in the legend to Fig 2.

ADP'ase) and PGI$_2$ (50 ng/mL), and finally resuspended in 20 mL of buffer B without apyrase, PGI$_2$ and EGTA, but with CP (1 mmol/L), CPK (10 U/mL) and CaCl$_2$ (0.1 mmol/L). PPP at a final concentration of 5% was added 1 minute before the stimulus.

Protein phosphorylation. PRP from 120 mL of blood—after aspirinization and addition of PGI$_2$ (20 ng/mL)—was centrifuged. Platelets were resuspended in 2 mL autologous PPP containing apyrase (3 U/mL ADP'ase) and 1 μmol/L PGE$_1$, and they were incubated with 8 to 10 mCi ^{32}P for 1.5 hours at 37°C. Then 20 mL of prewarmed (37°C) buffer A containing PGI$_2$ (50 ng/mL) was added, and platelets were pelleted by centrifugation (800 g for 10 minutes). Platelets were resuspended in 15 to 20 mL buffer without EGTA or PGI$_2$ but with apyrase (0.6 U/mL ADP'ase) and 5% PPP. The platelet suspension was kept at room temperature. Samples (0.6

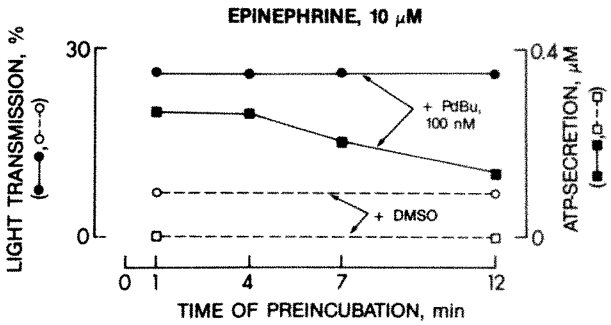

Fig 7. Effect of time of platelet pretreatment with PdBu on epinephrine-induced platelet responses in PRP. Platelet responses were measured 2 minutes after addition of epinephrine.

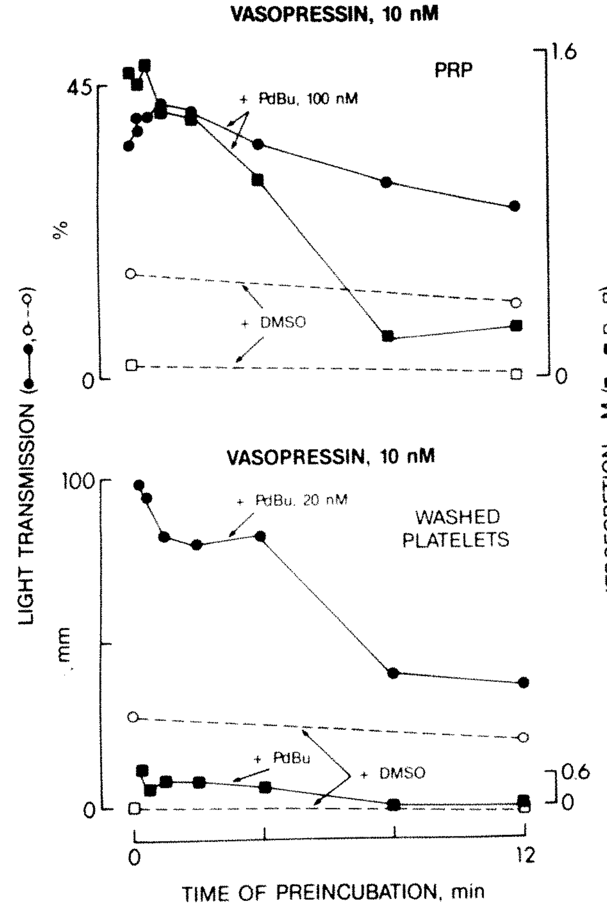

Fig 8. Comparison of platelet sensitization by PdBu on responses of PRP and washed platelets induced by vasopressin—effect of time length of platelet pretreatment with PdBu. Details are given in the Materials and Methods section.

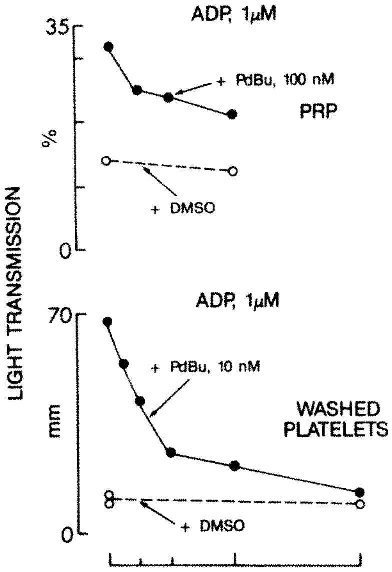

Fig 9. Effect of time of pretreatment with PdBu on responses of PRP and washed platelets induced by ADP.

mL) were transferred into aggregometer cuvettes and incubated with PdBu, 4-α-PDD or DMSO (1 μL) for 10 seconds to 10 minutes at 37°C before addition of the platelet stimulus. Aliquots (0.05 mL) were transferred into 0.05 mL of sample buffer containing 1% sodium dodecyl sulfate (SDS) and dithiothreitol (15 mg/mL) for measurement of protein phosphorylation. Phosphorylation of ^{32}P-labeled proteins was measured after separation on SDS-polyacrylamide (12.5%) gel electrophoresis (PAGE).[17]

Platelet aggregation and secretion. Platelet aggregation was measured using either a single-channel aggregometer adjusted to maximal sensitivity or a Lumi-Aggregometer (Chronolog, Havertown, PA). The Lumi-Aggregometer was calibrated in studies using PRP with autologous PPP (0.4 mL) and in studies using washed platelets with 0.3 mL platelet suspension diluted with 0.1 to 0.2 mL buffer. ATP secretion was measured in the Lumi-Aggregometer after addition of 0.04 mL of a mixture of Luciferin/Luciferase (Chronolog). PdBu or TPA (dissolved in DMSO) was added in small volumes (1 to 2 μL) using an Eppendorf microliter pipette.

Arachidonate metabolites. For measurement of production of arachidonate and arachidonate metabolites, PRP (50 mL) was centrifuged after addition of PGI_2 (50 ng/mL), resuspended in 5 mL PPP containing 1 μmol/L PGE_1 and apyrase (0.6 U ADP'ase/mL) and incubated with 100 μCi of [^{3}H]arachidonic acid (added in 0.02 mL ethanol) for 1.5 hours at 37°C. Platelets were centrifuged, washed twice with buffer A containing 10% PPP, apyrase, and PGI_2 (50 ng/mL) and resuspended in buffer B containing 10% PPP. $CaCl_2$ (0.1 mmol/L) was added 1 minute before the stimulus. Samples (0.5 mL) were stirred in the aggregometer at 37°C, and aliquots (0.1 mL) before (control) and 1 minute after addition of the stimulus were transferred into 0.6 mL of 3% glutaraldehyde/100 mmol/L $NaHPO_4$. Platelets were pelleted using a microfuge (12,000 g for 2 minutes), and the supernatant was counted for ^{3}H-radioactivity.

Data analysis. Data are shown for single experiments typical of at least three similar experiments. The extent of aggregation is either expressed as deflection of the recording pen in millimeters (when the more sensitive aggregometer was used) or in percent change of light transmission (when the Lumi-aggregometer was used). The rate of aggregation and secretion was estimated measuring the initial slope of the curves plotted against a time interval of 30 seconds.

RESULTS

Studies in PRP. PdBu (200 nmol/L) added to aspirinized platelets suspended in plasma containing CP/CPK induced a slow, limited aggregation response that started 45 to 60 seconds after addition. No ATP secretion was observed (Fig 1). If PdBu was added 5 to 15 seconds before or simultaneously with platelet stimuli such as epinephrine, endoperoxide analog U44069, collagen, vasopressin, PAF, or ADP, the rate and extent of both aggregation and ATP secretion induced by those agonists were greatly enhanced (Figs 1 through 6 and 10, Table 1). Also, PdBu (100 nmol/L) added to normal untreated citrated PRP, potentiated platelet aggregation induced by various agonists (Table 2). The potentiation of platelet aggregation and secretion by PdBu in response to epinephrine was unique, because it was observed at both low and high concentrations of epinephrine (Figs 2 and 11). Epinephrine alone induced only a small primary aggregation without ATP secretion (Fig 1). The PdBu-induced sensitization of platelets toward the other platelet stimuli was more pronounced when their concentrations were low (Figs 3 through 6). Time-course studies and

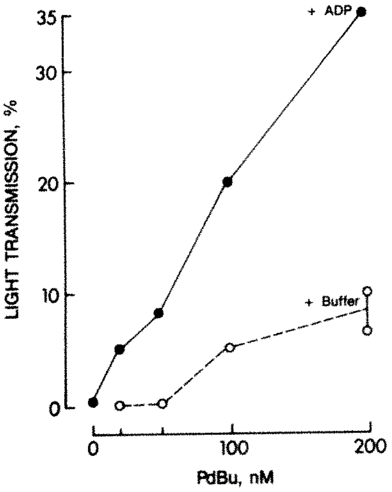

Fig 10. Potentiation of ADP-induced platelet aggregation by various concentrations of PdBu. ADP (0.5 μmol/L) or buffer was added 5 seconds after PdBu to PRP containing aspirin (1 mmol/L). Aggregation was measured 3 minutes after addition of ADP. ADP (0.5 μmol/L) alone induced shape change without aggregation.

Table 2. Potentiation of Stimulus-Induced Platelet Aggregation in PRP by PdBu

Stimulus	Aggregation (% Light Transmission) DMSO	4α-PDD	PdBu
Control	0	0	22 ± 1
Epinephrine 1 μmol/L	46 ± 3	48 ± 2	80 ± 4
ADP 0.5 μmol/L	44 ± 5*	43 ± 1*	83 ± 2
PAF 20 nmol/L	22 ± 4*	16 ± 2*	53 ± 2
Vasopressin 100 nmol/L	27 ± 2*	25 ± 2*	71 ± 3

Untreated citrated PRP (0.5 mL, 37 °C) was incubated for 10 seconds with either DMSO (1 μL), 100 nmol/L 4α-phorbol 12,13-didecanoate (4α-PDD) or 100 nmol/L PdBu before addition of various platelet stimuli. Aggregation was recorded for 1 minute using a Lumi-Aggregometer. For increase of sensitivity, the PPP cuvette contained 0.2 mL PPP plus 0.4 mL PRP. Results show triplicate values (mean ± SD) of one of three typical experiments.

*Reversible aggregation.

dose–response curves for the different platelet stimuli in the presence or absence of PdBu show that platelet aggregation was the first response potentiated by PdBu (Figs 1 and 3 through 6). Potentiation of ATP secretion by PdBu occurred at higher concentrations of the platelet stimulus and could even be observed at agonist concentrations that were maximal for aggregation (Figs 2 through 6). 4α-Phorbol and 4α-phorbol 12,13-didecanoate, inactive parent compounds of PdBu, were ineffective at inducing potentiation of platelet aggregation and ATP secretion (Figs 5 and 11 and Table 2).

Reversible aggregation responses induced by low concentrations of vasopressin, PAF, U44069, or ADP became irreversible in the presence of PdBu. The irreversibility of aggregation did not seem to depend on secretion, because irreversible aggregation induced by low concentrations of U44069 plus PdBu was not associated with ATP secretion, and reversible aggregation induced by PAF (1 μmol/L) was accompanied by ATP secretion (Figs 3 and 6).

The potentiating effect of phorbol ester on stimulus-induced aggregation was dependent on the concentration of the phorbol ester used (Figs 10 through 13). Although both PdBu and TPA induced potentiation of platelet aggregation in PRP, differences between those two active phorbol esters exist. At equimolar concentrations (60 nmol/L), TPA was more effective than PdBu at inducing a significant aggregation response (30% increase of light transmission at 3 minutes). The potentiation of vasopressin or ADP-induced platelet aggregation (measured after 1 minute) was more pronounced, however, for PdBu than for TPA. The TPA-induced potentiation of platelet aggregation was more evident at later times (≃2 minutes after addition of platelet stimuli) and concerned the extent rather than the velocity of the aggregation response (data not shown).

The length of time of platelet preincubation with PdBu on the potentiation of platelet responses had different effects dependent on the type of agonist used. Upon platelet stimulation with epinephrine, preincubation with PdBu for even 12 minutes did not diminish its synergistic effect on platelet aggregation (Fig 7). In contrast, if vasopressin, ADP or U44069 were used as platelet stimuli, the sensitizing effect of PdBu on platelet aggregation decreased with increasing time of platelet preincubation with PdBu (Figs 8 and 9; data for U44069 are not shown). But even following preincubation of platelets with PdBu for 12 minutes the extent of aggregation induced by low concentrations of vasopressin or U44069 was still higher than in the absence of PdBu (Fig 8). The rate of

Table 1. Rate of Aggregation and Secretion Induced by Vasopressin Plus PdBu is Dependent on the Preincubation Time with PdBu

Stimulus (10 nmol/L)	Time of Preincubation With PdBu	Rate of Aggregation Δ% Light Transmission (per 30 s)	Rate of Secretion ΔμM ATP (per 30 s)
Vasopressin	—*	16	0.03
Vasopressin	5 seconds	20	1.3
Vasopressin	30 seconds	22	1.1
Vasopressin	1 minute	22	0.9
Vasopressin	2 minutes	21	0.9
Vasopressin	4 minutes	20	0.8
Vasopressin	8 minutes	15	0.13
Vasopressin	12 minutes	12	0.10

PRP preincubation with PdBu (100 nmol/L) at 37 °C for the times indicated before addition of vasopressin.

*No PdBu.

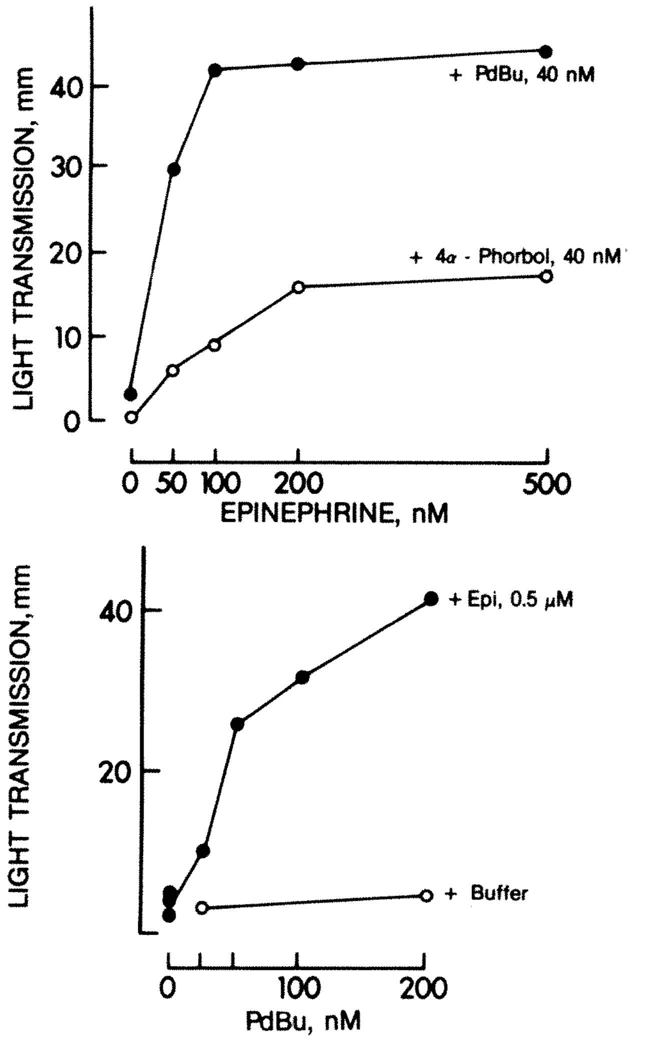

Fig 11. Potentiation of epinephrine-induced platelet aggregation by PdBu. Upper panel: Epinephrine concentration curve. Results obtained with 4α-phorbol were similar to controls. Lower panel: PdBu concentration curve. Both curves were obtained from the same experiment. Conditions were the same as those described in the legend to Fig 10.

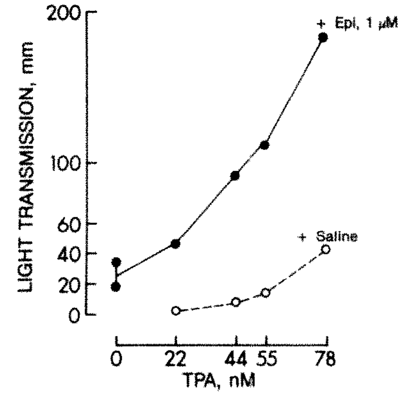

Fig 12. Potentiation of epinephrine-induced platelet aggregation by TPA. Conditions were the same as those described in the legend to Fig 10.

platelet aggregation returned to control levels after prolonged platelet pretreatment with PdBu (Table 1). The potentiation of ATP secretion by PdBu diminished with increasing time of platelet pretreatment with PdBu. The decrease in the secretory response was more rapid than the decrease in aggregation and was observed for all platelet stimuli tested (epinephrine, vasopressin, and U44069).

Studies in washed platelets. Similarly, PdBusensitized platelets toward agonists in suspensions of washed aspirinized platelets suspended in buffer containing 5% PPP and CP/CPK (Figs 8, 9 and 14). The effective concentrations of PdBu (20 to 40 nmol/L) were 5 to 10 times lower than the concentrations needed in PRP. In comparison with the studies in PRP, the sensitizing effect of PdBu disappeared more rapidly in washed platelets with increasing time of PdBu pretreatment. Only upon platelet stimulation with epinephrine was the potentiating effect of PdBu sustained, even if platelets were preincubated for 12 minutes before epinephrine was added (Fig 14). PdBu added to aspirinized as well as to nonaspirinized washed platelets enhanced aggregation and ATP secretion in response to vasopressin, epinephrine, and collagen. PdBu did not, however, increase the stimulus-induced production of arachidonate plus metabolites under these conditions (Table 3).

Protein phosphorylation studies showed that PdBu (20 nmol/L) added to suspensions of washed platelets containing 5% PPP induced only a relatively small activation of protein kinase C. The phosphorylation of the 40-kd protein increased by 20% to 90% over control dependent on the time length of incubation with PdBu (Fig 15). Subsequent addition of vasopressin potentiated protein kinase C activation as reflected by an increase in 40-kd protein phosphorylation (Fig 15). This potentiation was associated with potentiation of platelet aggregation (Fig 15A through C). With increasing preincubation times for PdBu, the potentiation of protein kinase C activation slowed and platelets started to get desensitized to vasopressin (Fig 15D). The potentiation of protein kinase C activation correlated with a reduction of myosin light chain phosphorylation (Fig 15). Vasopressin-induced myosin light chain phosphorylation was increasingly

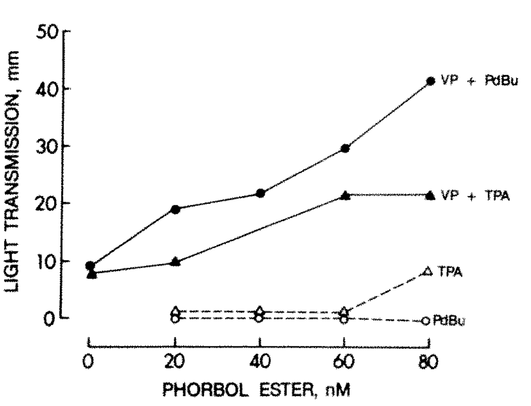

Fig 13. Potentiation of vasopressin (50 nmol/L)-induced platelet aggregation by PdBu or TPA. Aggregation was measured 1 minute after addition of vasopressin. Conditions were the same as those described in the legend to Fig 10.

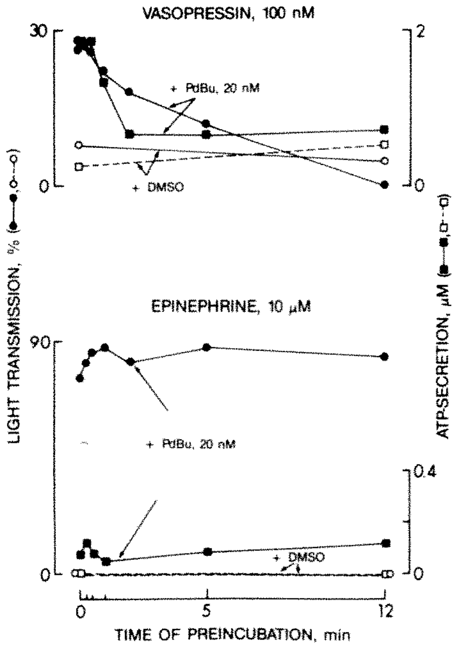

Fig 14. Effect of time of pretreatment with PdBu on responses of washed platelets stimulated by vasopressin or epinephrine.

reduced, if platelets were preincubated for 10 seconds, 1 minute, 5 minutes or 10 minutes with PdBu before addition of vasopressin (Fig 15). These results indicate that potentiation of vasopressin-induced platelet aggregation by PdBu correlated with potentiation of protein kinase C activation and reduction of myosin light chain phosphorylation.

DISCUSSION

Our study indicates that pretreatment of platelets with phorbol esters for various times sensitizes platelets to aggregate and secrete upon stimulation by a wide variety of physiological platelet agonists. This result is surprising, because many studies have demonstrated that phorbol esters desensitize receptor-mediated responses in various cell types, including platelets.[3-12] Most of those studies were performed after the cells were isolated from their physiologic environment and resuspended in an artificial medium. Our study clearly shows that platelets resuspended in plasma show an increased aggregation and secretion response to agonists when they are preincubated with phorbol ester. Enhanced platelet responses could even be observed when the preincubation time with PdBu was extended to 12 minutes. The sensitization became less pronounced by increasing the time of platelet preincubation with PdBu. Using washed platelets resuspended in buffer containing plasma (5%), platelets were also sensitized by pretreatment with phorbol ester, but the sensitizing effect disappeared more rapidly than with PRP.

Our protein phosphorylation studies indicate that the potentiation of platelet aggregation and secretion correlated with a potentiation of protein kinase C activation, but myosin light chain phosphorylation was reduced (Fig 15). These results indicate that protein kinase C stimulation induced during platelet activation is a positive signal for aggregation and secretion, although other proximal biochemical responses such as phospholipase C activation, Ca^{2+} mobilization (data not shown), and myosin light chain phosphorylation (Fig 15) are reduced. It is particularly important for the interpretation of our results that PdBu—although added at relatively high concentrations to PRP (100 or 200 nmol/L) or washed platelets (20 or 40 nmol/L)—induced only a small activation of protein kinase C even after a prolonged preincubation (10 minutes) with platelets. Under our more physiologic experimental conditions (presence of plasma, discoid platelets) protein kinase C in platelets may not be readily accessible to exogenous PdBu. On addition of platelet stim-

Table 3. Effect of PdBu on Stimulus-Induced Production of Arachidonate and Arachidonate Metabolites, Aggregation and ATP Secretion in Control and Aspirinized Platelets

Platelets	Aggregation (mm)	ATP Secretion (μM ATP)	Arachidonate Plus Metabolites in Supernatant (cpm ^{3}H-radioactivity)
Nonaspirinized platelets			
Control	0	0	1884 ± 88 (10)

Collagen plus PdBu	18 ± 2	3.18 ± 0.25	4397 ± 319 (3)

Aggregation and ATP secretion were measured after 1 minute; production of AA metabolites was measured 1.5 minutes after addition of platelet stimuli.

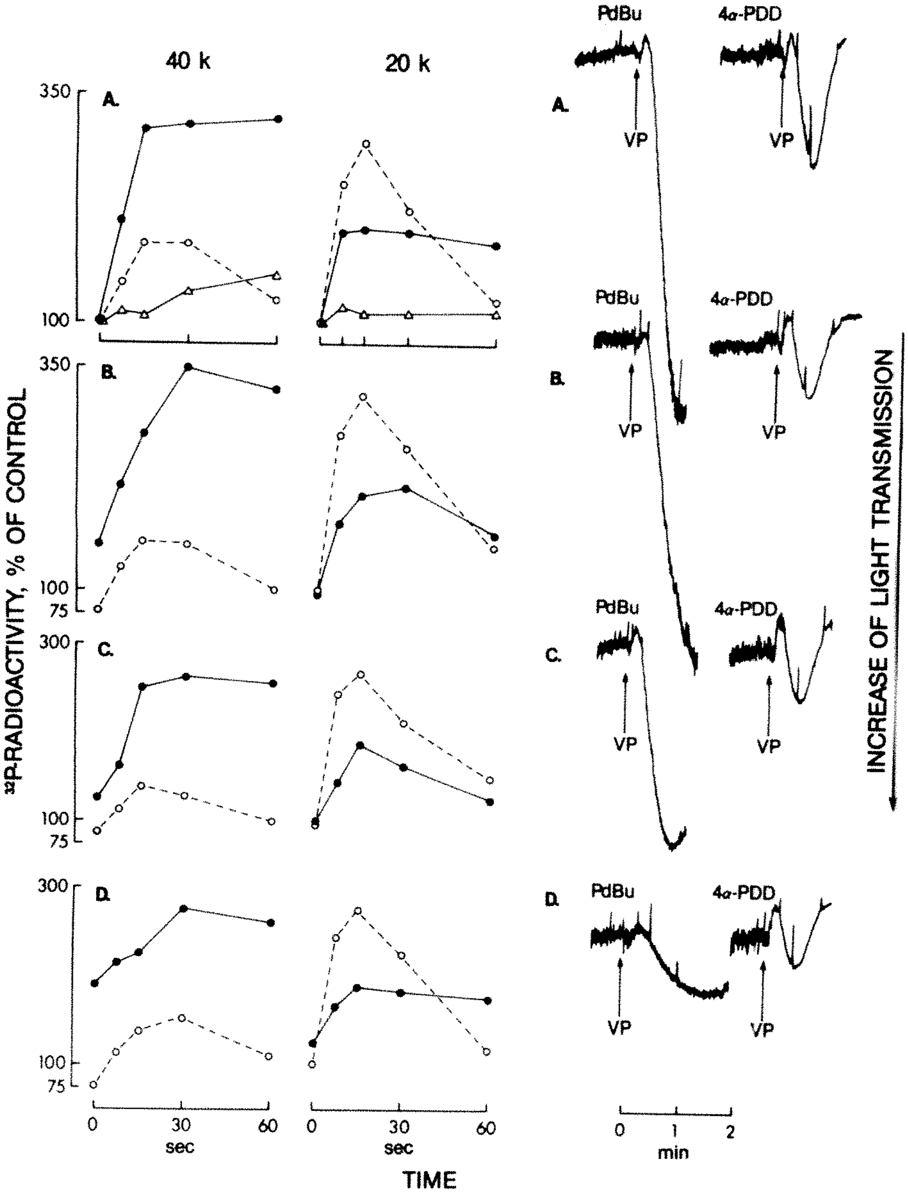

Fig 15. Protein phosphorylation (left) and aggregation tracings (right) of washed platelets pretreated for various time lengths with PdBu (●—●) or 4 α-PDD (○---○) before the addition of vasopressin (VP). Suspensions (0.6 mL) of aspirinized ^{32}P-labeled platelets containing apyrase and 5% plasma were preincubated for 10 seconds (A), 1 minute (B), 5 minutes (C), or 10 minutes (D) at 37°C with 4α-PDD (○---○, 20 nmol/L) or PdBu (●—●, 20 nmol/L) before the addition of VP (50 nmol/L). Stirring was started 30 seconds before addition of VP. Protein phosphorylation (left) was measured in 0.05-mL aliquots of the samples whose aggregation tracings are shown at the right. Protein phosphorylation induced by addition of PdBu alone during stirring is shown in A. The samples containing 4α-PDD gave results identical to those of controls.

uli, however, protein kinase C becomes accessible to phorbol esters. The results further show that small preactivation of protein kinase C is not sufficient to induce desensitization of stimulus-induced functional platelet responses. In previous studies that showed desensitization of stimulus-induced aggregation and secretion by phorbol ester,[4-6,9-11] protein kinase C might have been readily accessible to phorbol esters and maximally activated.

The platelet-aggregating effect of phorbol ester was first described by Zucker et al,[18] who observed, on addition of TPA, a slow, delayed aggregation response of PRP that was not blocked by aspirin or ADP scavengers. We observed that PdBu (100 nmol/L) induced a more significant aggregation response if added to untreated PRP (Table 2) than if added to platelets pretreated with aspirin and PGI_2 and resuspended in plasma in the presence of ADP scavengers (Fig 1). Previous studies clearly show that protein kinase C activation itself does not cause platelet aggregation and secretion.[1,2] In the present study, we observed very little protein kinase C activation by PdBu. Mobilization of membrane-bound Ca^{2+} by phorbol esters, as measured in aequorin-loaded platelets,[19] may be more important for platelet aggregation induced by phorbol esters. Phorbol ester-induced Ca^{2+} mobilization[19] and aggregation but not protein phosphorylation (W. Siess and E.G. Lapetina, unpublished observations) is inhibited by elevation of platelet cyclic AMP levels.

The study shows a clear sensitization of platelet responses to physiologic agonists by phorbol ester. The potentiation of protein kinase C activation may act synergistically with the Ca^{2+} mobilization induced by physiologic agonists and be responsible for the potentiation of aggregation and secretion. Because no attenuation of stimulus-induced functional platelet responses has been found, the desensitization by protein kinase C activation of signal transduction mechanisms (inositol phospholipid hydrolysis, Ca^{2+} mobilization, myosin light chain phosphorylation) might not have been sufficient to be physiologically relevant. On the basis of differences for the various agonists in the dose–response curves and in the decrease of sensitization with increasing time of preincubation of platelets with phorbol ester, two different mechanisms underlying the observed synergism of phorbol ester with platelet stimuli are proposed. One mechanism involves the synergism of phorbol ester with epinephrine, which is not related to potentiation of protein kinase C activation.[20] The other underlies the synergism of phorbol ester with the other agonists, which is related to potentiation of protein kinase C activation. In this regard, it is interesting that epinephrine, in contrast to all other agonists, does not cause phospholipase C activation.[16,21]

Bone Marrow Transplantation for Leukemia Following a New Busulfan and Cyclophosphamide Regimen

By Peter J. Tutschka, Edward A. Copelan, and John P. Klein

Busulfan 16 mg/kg and cyclophosphamide 120 mg/kg were used as conditioning prior to allogeneic marrow transplantation in 50 adult patients with acute nonlymphocytic leukemia (ANLL), acute lymphocytic leukemia (ALL), and chronic myelogenous leukemia (CML). A standard risk group of 20 patients included those with acute leukemia in remission and CML in chronic phase. A high-risk group of 30 patients included individuals with refractory acute leukemia, acute leukemia in relapse, acute leukemia following preleukemia, and CML in accelerated and blastic phase. Complete remission and sustained complete engraftment were achieved in all evaluable patients. The duration of aplasia was remarkably short (median of 8 days), resulting in a low infection rate during the period of neutropenia, a reduced need for blood product support, and a short length of hospital stay. Three-year actuarial relapse-free survival in both standard-risk (88.9% ± 10.5%) and high-risk (50.5% ± 9.6%) groups compares favorably with that reported with total body irradiation (TBI) containing regimens.

© 1987 by Grune & Stratton, Inc.

ALLOGENEIC BONE MARROW transplantation following total body irradiation (TBI) and high-dose chemotherapy has provided encouraging therapeutic results in patients with hematologic malignancies.[1] Apparent cure of $\sim$50% of patients with acute nonlymphocytic leukemia (ANLL)[2] in first remission and chronic myelogenous leukemia (CML) in chronic phase has been achieved[3]; the success rate in acute lymphocytic leukemia (ALL) has been somewhat lower.[4] Despite these results, several undesirable features of allogeneic marrow transplantation have limited its application.[5] First the usual side effects of the conditioning regimen together with prolonged periods of isolation often make transplantation a difficult ordeal for the patient. Second, common complications of marrow transplantation such as infections, graft-*v*-host disease (GVHD) and interstitial pneumonia (IP) may be lethal. Third, chronic complications such as chronic GVHD may result in a substandard quality of life despite a "successful" outcome. Last, relapse occurs in 10% to 40% of individuals transplanted under the best circumstances. These problems have understandably dampened the enthusiasm for this therapy.

The plateau in survival rates, observed over the recent past, may in large part reflect limitations of the traditional regimen of TBI and cyclophosphamide (Cy). Past attempts to replace TBI with chemotherapeutic agents have not met with an increased success rate.[6] In a previous trial using busulfan with higher doses of Cy than are commonly used with TBI, a significantly lower relapse rate for ANLL in remission was achieved. A higher complication rate, however, caused a similar overall long-term disease-free survival as compared with TBI-containing regimens.[7]

Because busulfan is the primary antileukemic agent in our regimen and because of the high complication rate in the previous trial, we used as a new conditioning regimen the same dose of busulfan but a lower dose of Cy. We describe the activity of this regimen in 50 consecutive adult patients transplanted with CML in chronic, accelerated, or blastic phase, and with ALL and ANLL in first or second remission, in relapse, or with refractory disease.

MATERIALS AND METHODS

All patients were entered on a study protocol that had been reviewed and approved by The Ohio State University Institutional Review Board.

Patient accrual. Fifty adult patients were consecutively entered into the study. Eligibility for the study required a diagnosis of ALL, ANLL, or CML, regardless of the remission status. All patients were ambulatory, had an HLA-identical sibling donor, and were aged >15 and ≤ 50 years. No other medical parameters were used as exclusion criteria. All diagnoses of leukemia were confirmed by examination of the bone marrow aspirate and biopsy. On admission, all patients had a bone marrow aspirate and bone marrow biopsy as well as a diagnostic lumbar puncture to assess the status of the leukemia. Presence of leukemic cells in the spinal fluid was not an exclusion criterion. All data are analyzed as of February 14, 1987. The patients were transplanted betwen February 13, 1984 and August 14, 1986; therefore, the observation period for these patients has been a minimum of 6 months and a maximum of 3 years.

Study groups. The study involved two groups of patients. A standard-risk group consisted of patients with acute leukemia in the first or second remission, or CML in the chronic phase. Twenty patients, 11 with ANLL in remission, 2 with ALL in remission, and 7 with CML in chronic phase were in this group.

The high-risk group consisted of 30 patients with refractory acute leukemia, acute leukemia in relapse, or CML in accelerated or blastic phase. Refractory acute leukemia was defined as leukemia that failed to remit after two courses of conventional chemotherapy. Patients were considered to be in the accelerated phase of CML if they had $\geq 10\%$ blasts in blood or marrow together with major perturbations of the leukocyte or platelet count unresponsive to chemotherapy with busulfan or hydroxuyrea. They were considered to be in the blastic phase if they had $\geq 30\%$ blasts in the blood or bone marrow. Among the patients in the high-risk group were two previously untreated patients in whom leukemia developed after a preleukemic syndrome (UPN 4 and UPN 17).

Twelve patients had ANLL, 4 had ALL, and 14 patients had CML in accelerated ($n = 9$), or blastic phase ($n = 5$).

Patient criteria. The median age of the recipients was 28 years (range 15 to 50 years). The median age of patients in the standard-risk group was 32 years (range 19 to 50 years), and the median age of

Blood, Vol 70, No 5 (November), 1987: pp 1382-1388

the high-risk group 27 years (range 15 to 48 years). Thirty-four patients were male and 16 patients were female. Thirty-four patients were sex matched with their recipients (20 male to male, 9 female to female transplants), and 16 patients were sex mismatched (6 male to female and 10 female to male transplants). All patients were identical for A, B, C, D/Dr locus with their allogeneic sibling donors. When possible, genotypical analysis of the entire family was performed. Seven patients had major blood group mismatches with their donors. The erythrocytes were removed from the marrow inoculum of these donors by centrifugation prior to the marrow infusion.[8]

Bone marrow donors. All donors were required to give informed consent prior to the procedure. All donations were carried out under general anesthesia. The technical aspects of the procedure have been described elsewhere.[9] All donors tolerated the marrow aspiration well and were discharged between 1 and 2 days after the marrow harvest. No significant complications of the marrow harvest procedure occurred.

Preparative regimen. All patients were given methotrexate intrathecally (10 mg/m^2 of body surface but not more than 12 mg total) ~10 days prior to marrow transplantation. Three patients who had central nervous system (CNS) leukemia at the beginning of the transplant procedure were given four intrathecal treatments of methotrexate. Patients received busulfan orally at a dose of 1 mg/kg of ideal body weight four times daily for 4 consecutive days for a total dose of 16 mg/kg. Cyclophosphamide at a daily dose of 60 mg/kg of ideal body weight was administered intravenously (IV) over a 1-hour period for 2 consecutive days. Bone marrow was infused 2 days after the final dose of Cy.

Supportive therapy. On the day of hospitalization, all patients were placed in ultraclean rooms equipped with HEPA-filtered laminar air flow. Patients were treated in strict isolation. "Sterile diet" with very low bacterial content was begun on day −4 together with oral Clotrimazole and oral Trimethoprim-Sulfamethoxazole. Nonabsorbable antibacterial antibiotics were not used. All patients had a double-lumen and a single-lumen right atrial catheter placed. All patients received IV a commercial immunoglobulin preparation (Sandoglobulin®) at a dose of 500 mg/kg every 2 weeks starting 1 week prior to transplant and ending at day 120 after transplant. The first 31 patients did not receive immunoglobulin after that time, but the 19 most recently transplanted patients were given the same immunoglobulin preparation monthly until day 365. In an attempt to prevent hemorrhagic viral gastroenteritis, the same immunoglobulin preparation was given orally at a daily dose of 50 mg/kg in four divided doses, starting at day 2 after transplant and maintained until day 28.[10] All blood products administered were derived from volunteer donors who had a negative antibody titer against cytomegalovirus.

Transplantation and evaluation of engraftment. The bone marrow was infused on day 8 through a right atrial catheter over 4 hours. All patients tolerated the infusion well. The mean number of nucleated marrow cells infused was $5.17 \times 10^8 \pm 0.25$ (±1 SE)/kg body weight of the recipient. This number was not corrected for peripheral blood contamination. Engraftment was assessed indirectly by peripheral blood counts and periodic marrow examinations. An average of four routine marrow examinations were carried out for each transplant course, the last one performed between 120 and 160 days (mean 147 days) after transplant. After that time, bone marrow examinations were only carried out if hematologic and cytogenetic parameters measured in the peripheral blood suggested the recurrence of leukemia. Engraftment was measured directly by cytogenetic markers, when available (sex or autosomal markers), RBC enzymes, and RBC antigens.

Determination of remission status posttransplantation. Patients were considered to be in complete remission (CR) after transplantation for acute leukemia if they showed a completely normal bone marrow and peripheral blood status together with the absence of lymphohematopoietic cells of recipient origin by cytogenetic analysis.

Patients were considered to be in complete remission after transplantation for CML if they showed a completely normal bone marrow and peripheral blood status together with the absence of lymphohematopoietic cells of recipient origin by cytogenetic analysis. Patients who showed the presence of the Philadelphia chromosome prior to transplantation required the complete and persistent disappearance of this chromosomal abnormality after transplantation to qualify for complete remission status.

GVHD. All patients received a combination of cyclosporine and methylprednisolone to prevent GVHD. Cyclosporine started 1 day prior to transplantation and was given as a continuous infusion of 5 mg/kg daily for 4 days. After that time, the dose of cyclosporine was reduced to 3 mg/kg given IV over 6 hours daily until day 14. From day 14 through day 35, the dose of cyclosporine was increased to 3.75 mg/kg given IV. Thereafter, cyclosporine was slowly tapered until day 180, after which time it was discontinued. At discharge, patients were given oral cyclosporine at a dose four times higher than the IV dose. Methylprednisolone was started on day 7 at a dose of 0.5 mg/kg/day. On day 14, the dose was increased to 1 mg/kg/day and was given until day 28. Then, until day 72, the methylprednisolone was slowly tapered. All patients received prophylaxis for CNS leukemia. Between day 70 and day 90 after bone marrow transplant, four intrathecal doses of 10 mg/m^2 each of methotrexate were administered over 2 to 4 weeks.

Acute GVHD was assessed according to the grading system described in the literature.[11] Chronic GVHD was assessed using descriptive criteria reported previously. Patients were assumed to have chronic GVHD if they had the typical features of the disease[12] and/or were given adrenal steroids after day 100. Patients with chronic GVHD were divided into three groups according to severity, grade 1 disease showing mild symptoms that resolve within 2 months, grade 2 showing mild symptoms that require 2 to 6 months for resolution without sequelae, and grade 3 disease showing marked symptoms that require >6 months of therapy.

Other common complications. Interstitial pneumonia was diagnosed when bilateral interstitial/alveolar infiltrates on chest x-ray were associated with hypoxemia (PO_2 on room air of ≤65 mm Hg). Hemorrhagic gastroenteritis was diagnosed when diarrhea of greater than 1,000 mL/day was present that was either bloody or maroon and persisted for >3 days.

Statistical analysis. Estimates of survival probabilities and the probability of being in remission were computed by using the product-limit estimates of Kaplan and Meier.[13] In estimating the probability of being in remission, we treated those patients who died free of leukemic disease as censored observations. A Cox's proportional-hazards analysis was performed in each of the clinical variables displayed in Tables 1 and 2. Significance was judged using the maximum likelihood chi-squared statistic.[14]

RESULTS

Early toxicity of the preparative regimen. The preparative regimen was generally very well tolerated. Mild nausea and vomiting were noted during busulfan administration in nine patients; the remaining patients all tolerated busulfan well. On the days during which Cyclophosphamide was administered, most patients experienced nausea and vomiting requiring antiemetic therapy. None of the patients developed severe oral mucositis, but most patients complained of mild sore throat between 7 and 11 days after

Table 1. Cytogenetic Analysis of Cells in Peripheral Blood

transplant. Of the 50 patients, 32 had no evidence of hemorrhagic cystitis. Eight showed minimal microscopic hematuria, 5 patients showed macroscopic hematuria, and 5 patients showed severe hemorrhagic cystitis. Clinical symptoms of venoocclusive disease occurred in one patient (UPN 37), but resolved without any sequelae.

Antileukemic effect. With the exception of one patient who died on day 2 (UPN 38), all patients experienced a complete remission. This includes all patients with refractory disease and those in blast crisis of CML.

None of the patients transplanted in the standard-risk group to date have shown evidence of relapse. Among the 30 patients in the high-risk group, five patients all transplanted for acute leukemia experienced a clinical relapse (UPN 2, 7, 22, 35, and 52). Of the 14 patients transplanted for CML in accelerated or blastic phase, only one patient has shown evidence of relapse by cytogenetic analysis (UPN 21). This patient, who developed recurrence of the Philadelphia chromosome in the marrow, was retransplanted using the same conditioning regimen. She is alive, disease-free 777+ days after the first transplant and 185+ days after the second transplant. The remaining 13 patients transplanted for CML in the accelerated or blastic phase to date remain in complete remission with a normal bone marrow and peripheral blood status, absence of the Philadelphia chromosome, and presence of lymphohematopoietic cells of exclusively donor type. A Kaplan-Meier product limit estimate for the probability of being in remission is shown in Fig 1.

Engraftment and marrow function. One patient who died on day 2 from cardiac failure (UPN 38) could not be evaluated for engraftment. One other patient (UPN 71) showed a recovery marrow on day 14, but never reached a WBC that exceeded $1.0 \times 10^9/L$ or a platelet count of $40 \times 10^9/L$. The remaining 48 patients all showed complete and sustained engraftment. The patients maintained a WBC level $>1.0 \times 10^9/L$ for a median of 5 days after marrow infusion, after which time most patients' counts fell precipitously. At a median of 13 days (range 10 through 35) they achieved a WBC level $>0.5 \times 10^9/L$ and a level $>1.0 \times 10^9/L$ at a median of 15 days (range 11 through 36). The median time to reach a self-sustaining platelet count of $40 \times 10^9/L$ was 19 days (range 11 through 38). Bone marrow biopsies obtained on day 14 after transplant showed the presence of all hemapoietic cell lines, including megakaryocytes in all patients except the one patient who could not be evaluated for engraftment (UPN 38).

Table 2. Clinical Parameters Associated With Survival (Cox-Hazards)

Hemorrhagic cystitis	2.584	0.68	0.0001	13.316

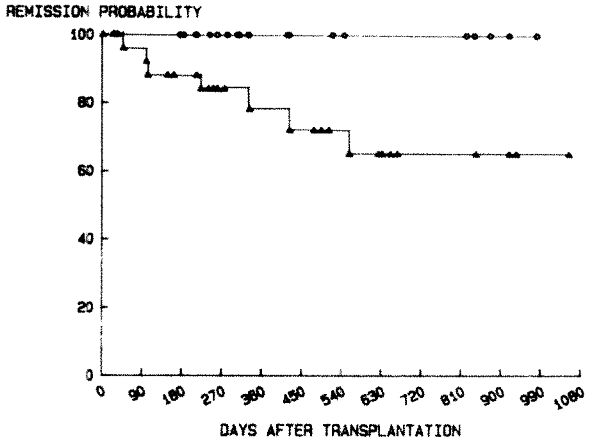

Fig 1. Probability of being in remission for patients transplanted in the standard-risk group *v* the high-risk group. Standard risk 100%, —○—; high risk 65.5% ± 11.1 (SE), —△—.

The degree of chimerism was assessed primarily by cytogenetic analysis. Cytogenetic analysis of the bone marrow was performed with each bone marrow aspirate. Cytogenetic analysis of the peripheral blood was performed every 2 weeks during the first 3 months and thereafter at each visit of the patient to the transplant center.

At day 14 after transplant, all patients had a marrow aspirate performed. Twenty-three patients showed technically sufficient cytogenetic preparations (14 sex markers and 9 autosomal markers) with a mean of 12.6 metaphases examined per patient. All cells identified cytogenetically at day 14 were of donor origin.

At least one second bone marrow examination was carried out, the latest performed at a mean of 123 days after transplantation. Twenty-six patients showed technically sufficient cytogenetic preparations with a mean of 18.4 metaphases examined per patient. Of these 26 patients, 24 had exclusively donor cells in their marrow. One patient (UPN 66) showed two of ten metaphases to be of recipient type at 71 days after transplant. He remains in complete remission on day 243+ after transplantation. One other patient (UPN 13) showed 1 of 17 cells to be of recipient type on day 446 after transplant. This patient, transplanted for CML in blast crisis, remains alive in complete remission on day 919+ after transplantation.

The cytogenetic analysis of the peripheral blood cells can be summarized as follows. Two hundred twenty-six samples were taken from 34 patients or an average of 6.64 samples per patient. The median number of samples per patient was 6.5 (range 1 to 15). Four thousand six hundred eleven cells were examined, an average of 20.40 per sample or 135.61 per patient. The number of cells per patient examined ranged from 13 (1 determination) to 390 (15 determinations). The median number of cells per patient examined was 115.5. The median number of cells per sample was 20 (range 1 to 50). The mode was 32. The median day of these examinations was 87.5 (range 12 to 767). The interquartile range was 117.5. Four thousand one hundred ninety-nine (4,199) of the cells examined were classified as donor cells (91.06% with an SE of .42%).

During the first 20 days, 85.4% of the cells were classified as donor. With time, the number of donor cells increased steadily until by day 365 after transplant only donor cells could be identified in the peripheral blood. A breakdown of the quantitative analysis over time is given in Table 1.

Support during the first 30 days after transplantation. Due to the brief period of aplasia, relatively few blood products were required to maintain a hemoglobin of ≥10 g/dL and a platelet count of ≥20 × 10^9/L. Patients transplanted in the high-risk group were given a median of 5 U RBCs (range 0 through 42) and five transfusions of single donor platelets (range 0 through 137). The patients transplanted in the standard-risk group received a median of 3 U RBCs (range 0 through 10) and a median of four transfusions of platelets (range 0 through 20). Eleven high-risk and eight standard-risk patients (38%) did not develop a temperature >100.5°F in the first 30 days and required no therapeutic antibiotics. Only one patient was given amphotericin-B for a fungal infection (UPN 71). One patient was documented to have bacteremia with *Pseudomonas aeruginosa* (UPN 43), probably derived from a cutaneous *Pseudomonas* abscess that antedated the transplant procedure. This patient responded promptly to appropriate antibiotic therapy. Two patients developed stomatitis with herpes simplex virus, which responded to Acyclovir. Three patients developed *Candida* esophagitis documented by endoscopy. All three responded promptly to oral nonabsorbable antifungal agents. Patients were discharged from the hospital when their granulocyte count was >0.5 × 10^9/L on three successive days and platelet and RBC counts were self-sustaining. Furthermore, they were required to be afebrile, off therapeutic antibiotics, and no longer receiving parenteral nutrition. The median day of discharge of all patients was 22 days (range 18 to 71), of the patients in the standard-risk group it was 21 days (range 18 to 33), and of the patients in the high-risk group it was 26 days (range 19 to 71).

GVHD. Acute GVHD was present in 15 patients. Of these fifteen patients, eleven showed grade 1 disease, one showed grade 2 disease, two showed grade 3 disease, and one showed grade 4 disease. All three patients with severe GVHD (grades 3 and 4) died in part from the GVHD. Chronic GVHD of grade 1 occurred in 5 patients, chronic GVHD of grade 2 occurred in 15 patients, and chronic GVHD of grade 3 occurred in 5 patients. Chronic GVHD resolved with no sequelae in all but two patients. Chronic GVHD was associated with death in 2 patients with grade 3 disease. Chronic GVHD has been completely absent to date in 16 of the 35 surviving patients. Of the 45 patients surviving 100 days, 19 or 42% have shown clinically significant chronic GVHD of grade 2 or greater at any time during their transplant.

Interstitial pneumonia and hemorrhagic gastroenteritis. Interstitial pneumonia occurred in six patients, four of whom died with the disease. In 2 patients cytomegalovirus could be identified by bronchoalveolar lavage, 2 patients had idiopathic interstitial pneumonia, and 1 patient each had pneumonia associated with *Legionella* and *Pneumoncystis carinii*. Two patients developed hemorrhagic gastroenteritis. In one of the two patients, hemorrhagic gastroenteritis was associated with severe GVHD, of which the patient died. The other patient recovered.

Late infections. Late infections (past day 50) occurred in 13 patients. Two patients developed systemic fungal infections (*Candida albicans*, UPN 24; *Aspergillus fumigatus*, UPN 19), and 12 patients developed bacterial infections, all with gram-positive organisms. Of these 12 bacterial infections, 8 were caused by *Streptococcus pneumoniae*, and 4 by *Staphylococcus epidermidis*. All bacterial infections presented with fever and minimal associated clinical symptoms and had documented bacteremia. Most bacterial infections (11 of 12) occurred after day 120 and have not been seen after IV immunoglobulin therapy was extended to 1 year posttransplant.

Survival. Of the 50 patients transplanted, 35 remain alive in unmaintained clinical remission. The actuarial 3-year survival rate of this patient population is 65%. The survival curves for all patients transplanted are shown in Figs 2 and 3. All patients in the standard-risk group transplanted for either ANLL or CML are disease-free survivors, and only 1 of the 20 patients transplanted in the standard-risk group (for ALL, UPN 19) has died. This death was associated with chronic GVHD and systemic *Aspergillus* infection, the patient being in complete remission at the time of death.

Of the 30 patients transplanted in the high-risk group, 16 are alive at present in unmaintained clinical remission. Nine of the 14 patients transplanted for CML in accelerated or blastic phase are alive, and 7 of the 16 patients transplanted for advanced acute leukemia are alive in unmaintained complete remission. The survival curves for these patient groups are shown in Figs 4 and 5.

Parameters affecting survival. Parameters that might

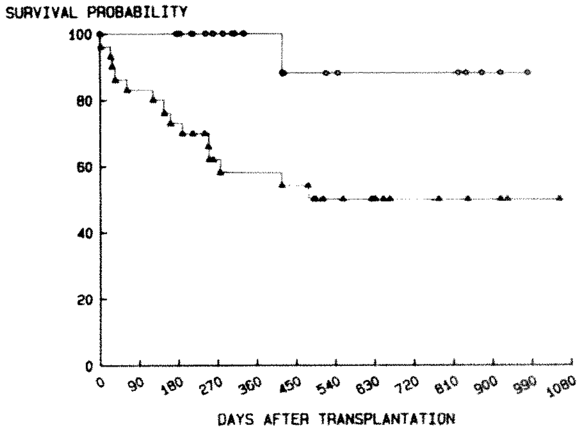

Fig 2. Probability of survival for patients transplanted in the standard-risk group v the high-risk group. Standard risk 88.9% ± 10.5 (SE), —O—; high risk 50.6% ± 9.6 (SE), —△—.

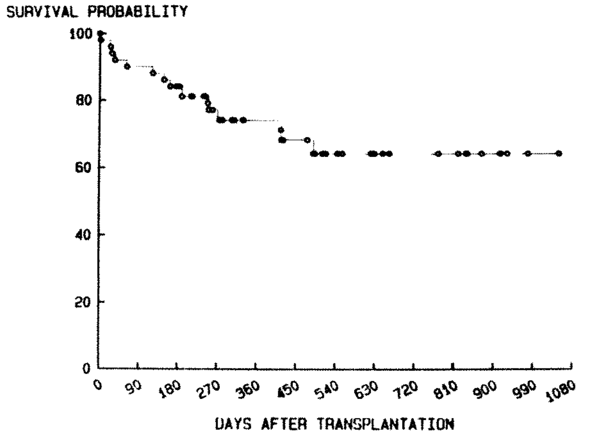

Fig 3. Probability of survival of all patients transplanted. Survival 64.9% ± 7.6 (SE), —O—.

affect survival were entered into a Cox regression proportional hazards model for death as outcome variable. The parameters included: diagnosis; disease status; risk group; age and sex of the recipient; time of return of blood counts; day of discharge; number of late infections; and the complications of hemorrhagic cystitis, hemorrhagic gastroenteritis, interstitial pneumonia, acute GVHD, and chronic GVHD. Refractory disease, interstitial pneumonia, hemorrhagic cystitis, and acute GVHD of grade 2 or greater were all significantly associated with death. These data are shown in Table 2.

DISCUSSION

Busulfan and Cy are an attractive combination for pretransplant conditioning. Preclinical studies in a rat model have demonstrated the importance of myelosuppression in combination with immunosuppression for preparing marrow graft recipients.[15] In this model, the addition of busulfan, a nonimmunosuppressive but highly myelotoxic agent, to Cy, a moderately myelotoxic but highly immunosuppressive agent, permitted the reduction of Cy without compromising engraftment.[16] Previous clinical trials using a combination of busulfan and high-dose Cy demonstrated excellent antileukemic efficacy, but serious toxicity similar to TBI-containing regimens.[6,7] The present study attempted to show that the reduction of Cy would not compromise antileukemic effectiveness of the combination, but would markedly reduce the complication rate. The reduction of Cy to 120 mg/kg, the commonly used dose in TBI-containing regimens, permitted furthermore the direct comparison of busulfan to TBI in the hope of achieving overall a lower complication rate.

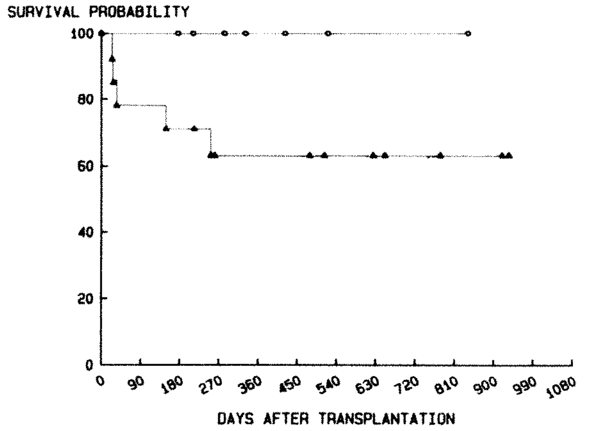

Fig 4. Probability of survival for patients transplanted for CML in the standard-risk group *v* the high-risk group. Standard risk 100%, —O—; high risk 63.5% ± 13.0 (SE), —△—.

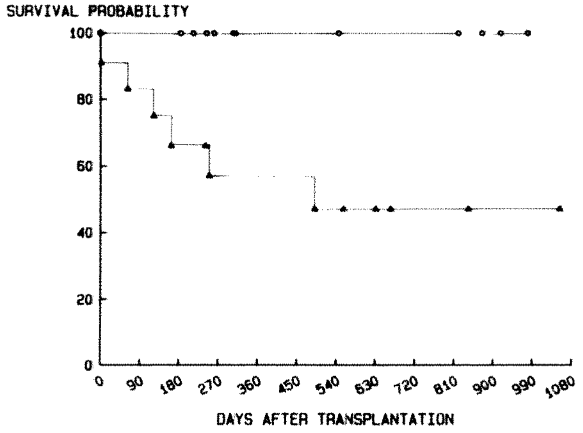

Fig 5. Probability of survival for patients transplanted for ANLL in the standard-risk group *v* the high-risk group. Standard risk 100%, —O—; high risk 47.6% ± 15 (SE), —△—.

The data presented in this report bear out these predictions. The preparative therapy was well tolerated, and apart from moderate yet transient nausea and vomiting associated with Cy, no immediate toxicity occurred. Apart from one patient who died too early for evaluation, all patients, including those with refractory leukemia or in blastic phase of CML, achieved complete remissions and complete sustained engraftment. As predicted from the animal model, marrow recovery occurred rapidly. Fully functioning hematopoietic grafts were usually achieved within the first 2 weeks after transplantation. It is tempting to speculate that the busulfan, by virtue of its "space making" properties, was responsible for this short aplasia.[6,16] It is equally possible, on the one hand, that the avoidance of TBI was less damaging to the microenvironment, permitting earlier engraftment. On the other hand, substituting cyclosporine and methylprednisolone for methotrexate in the prevention of GVHD might have reduced the induced aplasia after transplantation. This short period of aplasia resulted in a markedly reduced need for blood product support and, most important, in a surprisingly low incidence of infectious complications. There was a virtual absence of bacteremia (one patient) and only one patient required amphotericin-B administration. Other common complications, such as acute GVHD were also infrequent. The low incidence of severe acute GVHD may have resulted from prophylaxis with a new combination regimen of cyclosporine/methylprednisolone. The low incidence of early infectious complications resulting from short aplasia, lesser amounts of tissue toxicity, and ultraclean environmental conditions may have led to a reduced incidence of

GVHD, a postulate supported by a number of preclinical and clinical observations.[17,18]

It is unclear to what extent the reduced incidence of interstitial pneumonia can be credited to the preparative regimen. Because radiotherapy and acute GVHD contribute to the development of interstitial pneumonia,[19] the low incidence in our study is probably not just a spurious observation. Furthermore, the patients received IV immunoglobulin preparations and blood products derived from cytomegalovirus-antibody–negative donors, both procedures reportedly associated with a lower incidence of viral interstitial pneumonia.[20-22]

Late complications seen after allogeneic bone marrow transplantation were not altered in frequency when compared with TBI-containing regimens. Some patients developed gram-positive bacteremias after 100 days, none of which led to the death of the patients. These often quite insidious infections have not been observed since the administration of IV immunoglobulin was extended to 1 year posttransplant.

Similarly, chronic GVHD occurred frequently. Fortunately, this complication has been very mild and in most patients chronic GVHD has resolved completely without sequelae.

The antileukemic efficacy of this regimen is apparent. Although the disease-free survival in regular-risk patients so far is outstanding, clearly additional follow-up time is required to ascertain that these patients are indeed cured. The excellent results achieved in advanced disease demonstrate a potent antileukemic effect, however. The results in accelerated and blastic phase of CML compare favorably to published results in recent studies that use TBI and Cy.[3]

The patients studied here were at high risk for several reasons. They were older than patients in most comparable studies, some of our patients being 50 years old. Older age clearly increases the transplant risk.[2,3,23] Many had advanced disease, including high-risk factors such as pretransplant hepatic dysfunction, cytogenetic abnormalities, CNS disease, and cutaneous involvement, all parameters associated with poor prognosis.

The results of this study are encouraging. This regimen may be more effective and less toxic than TBI-containing regimens for patients generally considered to be good transplant candidates, eg, those with acute leukemia in remission and CML in chronic phase. In addition, this regimen offers promise in circumstances such as CML in accelerated or blastic phase and in refractory acute leukemia in which transplantation results have been so poor that valid questions as to the appropriateness of allogeneic marrow transplantation have been raised. Furthermore, the low toxicity of this regimen might permit the use of additional antileukemic agents in patients with advanced disease.

This report suggests that this new regimen provides an alternative to traditional conditioning regimens that include TBI. It offers substantial promise in decreasing the morbidity and improving the outcome of patients undergoing allogeneic marrow transplantation.

ACKNOWLEDGMENT

We thank the nursing staff of the Bone Marrow Transplant Unit and The Ohio State University Housestaff for their outstanding efforts. We are indebted to all referring physicians; to Dr Leona Ayers, head of Microbiology; to Phyllis Kaldor, head nurse of the Bone Marrow Transplant Unit; to Linda K. Graff, Transplantation Coordinator; to Becky Gibbins, Clinical Protocol Nurse; and Judy Bishop, Data Coordinator, for their many contributions. We thank Judy French and Barbara Fowls for preparing the manuscript and for numerous other contributions.

Effect of Oxalate and Malonate on Red Cell Metabolism

By Ernest Beutler, Linda Forman, and Carol West

The addition of oxalate to blood stored in Citrate-phosphate-dextrose (CPD) produces a marked improvement in 2,3-diphosphoglycerate (2,3-DPG) preservation; an increase in 2,3-DPG levels can also be documented in short-term incubation studies. Oxalate is a potent in vitro inhibitor of red cell lactate dehydrogenase, monophosphoglycerate mutase, and pyruvate kinase (PK). In the presence of fructose 1,6-diphosphate the latter inhibitory effect is competitive with phospho(enol)pyruvate (PEP). Determination of the levels of intermediate compounds in red cells incubated with oxalate suggest the presence of inhibition at the PK step, indicating that this is the site of oxalate action. Apparent inhibition at the glyceraldehyde phosphate dehydrogenase step is apparently due to an increase in the NADH/NAD ratio. Oxalate had no effect on the in vivo viability of rabbit red cells stored in CPD preservatives for 21 days. Greater understanding of the toxicity of oxalate is required before it can be considered suitable as a component of preservative media, but appreciation of the mechanism by which it affects 2,3-DPG levels may be important in design of other blood additives. Malonate, the 3-carbon dicarboxylic acid analogue of oxalate did not inhibit pyruvate kinase nor affect 2,3-DPG levels.

© 1987 by Grune & Stratton, Inc.

OVER A DECADE AGO it was demonstrated that ascorbic acid exerted a favorable effect on the 2,3-diphosphoglycerate (2,3-DPG) level of erythrocytes in stored blood.[1,2] Subsequent studies revealed that ascorbic phosphate, a more stable derivative of ascorbic acid had a similar effect.[3] Although this phenomenon has been confirmed repeatedly,[4-6] our investigation of the mechanism of the ascorbate effect failed to provide an explanation for the increase in 2,3-DPG that occurred.[1,7,8] Specifically, we could not find significant inhibition of glycolytic enzymes by ascorbate,[1] no evidence of oxidation of either NADH or NADPH, and no evidence that the ascorbate was metabolized or that it exerted a significant effect on intracellular pH.[7]

Recently, Kandler et al[9] found that in contrast to the usual preparations, highly purified ascorbic acid and ascorbic phosphate had no effect on the 2,3-DPG of stored red cells. Searching for a contaminant that might explain the effect of less purified batches, they discovered that oxalate found in the ascorbate preparations could account for the effect on the 2,3-DPG levels of red cells in stored blood.

We now report on the effects of oxalate on the metabolism of human erythrocytes, identifying some of the inhibitory actions that may explain the effect of this compound on 2,3-DPG levels. We have also explored the effect of malonic acid, a natural metabolic intermediate and the 3-carbon analogue of the 2-carbon dicarboxylic acid, oxalic acid, on 2,3-DPG levels.

MATERIALS AND METHODS

After obtaining informed consent, blood samples from normal blood donors were drawn into citrate-phosphate-dextrose (CPD), for storage studies at 4°C or into 1 mg/mL ethylenediamine tetracetic acid (EDTA) for short-term incubations at 37°C. Potassium oxalate and sodium malonate were purchased from Sigma Chemical Company, St. Louis.

Unless otherwise indicated red cell enzyme activities were measured using standard methods,[10] adding the stated amount of oxalate to the assay system. Pyruvate kinase (PK) activity was estimated using a system in which the generation of adenosine triphosphate (ATP) is measured in order to circumvent the inhibitory effect of oxalate on the lactate dehydrogenase reaction used as an indicator in the standard method. In this technique, the reaction mixture contained the following: 100 mmol/L Tris-HCl, pH 8; 0.5 mmol/L EDTA; 10 mmol/L $MgCl_2$, 100 mmol/L KCl; 0.2 mmol/L NADP; 2 mmol/L glucose; 1.5 mmol/L adenosine diphosphate (ADP); 0.1 U each of glucose-6-phosphate (G-6-P) dehydrogenase and hexokinase. The reaction was started by the addition of phospho(enol)pyruvate (PEP) to provide a concentration of 5 mmol/L. The effect of oxalate on the kinetics of the PK reaction were studied using partially purified PK.[11] Diphosphoglycerate phosphatase (DPGP) activity was measured by estimating inorganic phosphate (P_i) release from labeled 2,3-DPG.[12]

ATP, 2,3-DPG, and pyruvate and lactate levels were measured spectrophotometrically as previously described.[10] G-6-P, fructose-6-phosphate (F-6-P), fructose-1,6-diphosphate (FDP), dihydroxyacetone phosphate (DHAP), glyceraldehyde-3-phosphate (GAP), 3-phosphoglyceric acid (3-PGA), 2-phosphoglyceric acid (2-PGA), and PEP were all measured fluorometrically.[10] In some instances, the levels of DHAP, GAP, and FDP were sufficiently elevated in the erythrocytes so that their levels could also be measured by a spectrophotometric modification of the standard fluorometric technique. The internal pH of stored red cells was measured at 4°C using a Corning model 150 with a glass electrode, packing the erythrocytes by centrifugation, freezing, and thawing. Red cell viability was studied in New Zealand white rabbits using the combined ^{99m}Tc-^{51}Cr method.[13]

RESULTS

Cold storage of CPD anticoagulated blood with and without oxalate. Four hundred fifty milliliters of blood

from each of four normal donors was collected into 63 mL of CPD and into CPD containing sufficient potassium oxalate to provide a final concentration of 500 μmol/L. The blood was stored at 4°C, mixed at intervals, and the levels of ATP and 2,3-DPG were determined. The results of these investigations are shown in Fig 1. There was no difference in internal red cell pH for the first 2 weeks of storage. At 3 weeks the internal pH of the samples with oxalate averaged 0.061 U higher and at 4 weeks 0.11 U higher than the controls. The initial determination of red cell ATP and 2,3-DPG levels was made after the anticoagulated blood had been held at room temperature for approximately two hours. It was apparent that ATP levels in blood collected into oxalate-containing anticoagulants had already declined substantially in this brief time. This immediate effect of oxalate on red cell ATP levels was confirmed in other studies (data not shown). Over the 4-week storage period oxalate greatly improved preservation of 2,3-DPG but had a markedly deleterious effect on ATP levels. The same experiment was carried out with a final oxalate concentration of only 50 μmol/L. The results of this study are shown in Fig. 2.

The effect of oxalate on red cell enzyme activities. The effect of 500 μmol/L potassium oxalate on red cell enzyme activities is summarized in Fig 3. The enzyme most sensitive to inhibition by oxalate was found to be lactate dehydrogenase (LDH), followed closely by monophosphoglyceromutase (MPGM) and then by PK. In contrast to the effect of oxalate, 5 mmol/L malonate failed to inhibit erythrocyte MPGM, PK, or LDH activity. The effect of oxalate on PK kinetics is shown in Fig 4. The inhibition of PK by oxalate was competitive with PEP in the presence of FDP, the allosteric effector of PK, but noncompetitive in the absence of FDP.

The effect of oxalate on red cell metabolism at 37°C. Estimation of the levels of metabolic intermediates other than ATP and 2,3-DPG at the end of the 28-day storage period proved to be unreliable because of the very large amounts of pyruvate and lactate that had accumulated.

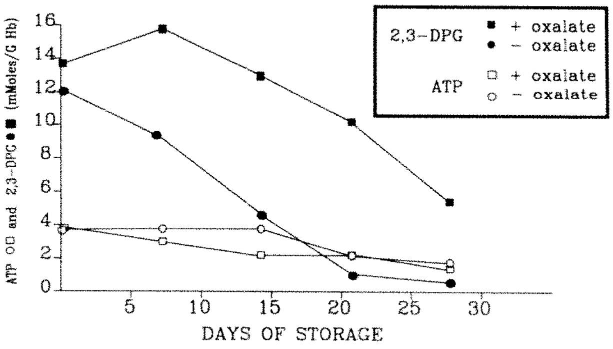

Fig 2. The same as Fig 1, except that the oxalate concentration was only 50 μmol/L.

However, studies of the effect of oxalate on red cell intermediates could readily be carried out on red cells incubated in autologous plasma for several hours at 37°C, since a rise in the red cell 2,3-DPG level was demonstrable under these conditions. It was necessary to use an anticoagulant other than CPD for such studies, because of the very substantial effect that temperature exerts on the pH of blood. It is ~0.7 pH units higher at 4°C than at 37°C[14] and the citrate preservatives provide an unsuitable medium for study of metabolism at the latter temperature. A suspension of red cells in EDTA anticoagulated plasma incubated under a suitable CO_2-air atmosphere is very suitable for such investigations. Preliminary studies showed that maximum elevation of red cell 2,3-DPG levels could be observed after four to six hours incubation at 37°C and that the amount of phosphate in plasma was insufficient to support an optimal effect of oxalate on 2,3-DPG concentration.

Erythrocytes from blood drawn into EDTA anticoagulant were resuspended at a hematocrit of 30% in their own plasma. Sufficient KH_2PO_4/K_2HPO_4 pH 7.4 was added to provide a 2.5 mmol/L increase in PO_4 concentration. Aliquots of the cell suspension were incubated at 37°C in a shaking incubator in an atmosphere of 5% CO_2/95% air with

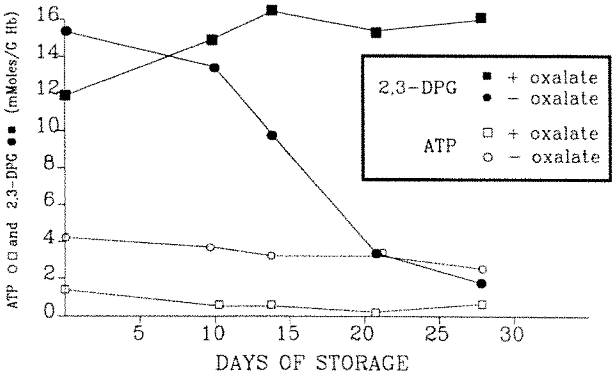

Fig 1. 2,3-DPG and ATP levels of blood stored in CPD (○, ●) and CPD plus sufficient oxalate to provide a final concentration of 500 μmol/L (□, ■). Four 450 mL units of blood were studied. Each point represents the mean of two observations. The 0 time points were obtained after a one to two hour holding period at room temperature. Following this the samples were stored at 4°C and mixed only at the time of sampling.

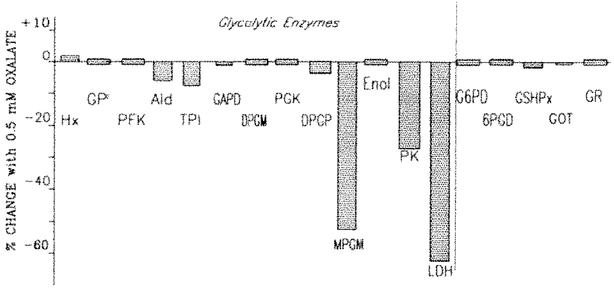

Fig 3. The effect of 500 μmol/L oxalate on the activity of some red cell enzymes. Abbreviations: Hx, hexokinase; GPI, glucose phosphate isomerase; PFK, phosphofructokinase, ALD, aldolase, TPI, triose phosphate isomerase; GAPD, glyceraldehyde phosphate dehydrogenase; DPGM, diphosphoglycerate mutase; PGK, phosphoglycerate kinase; MPGM, monophosphoglycerate mutase; Enol, enolase; LDH, lactate dehydrogenase; G6PD, glucose-6-phosphate dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; GSHPx, glutathione peroxidase; GOT, glutamate oxalocetate transaminase; GR, glutatione reductase.

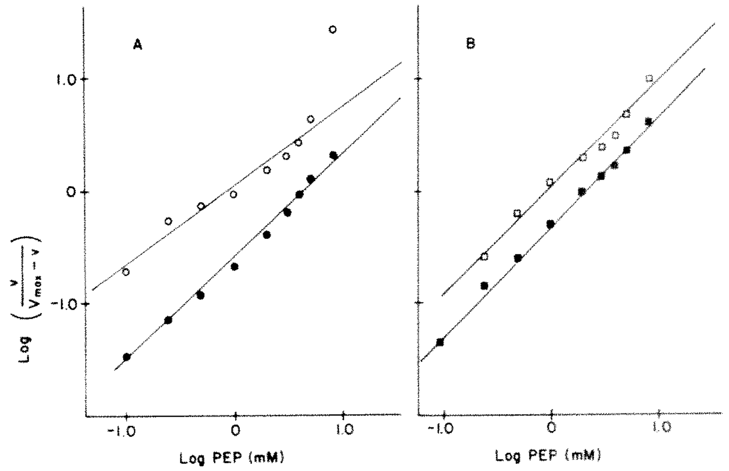

Fig 4. The kinetics of the inhibition of PK by 500 μmol/L oxalate. Hill plots are presented (A) in the presence of 500 μmol/L FDP, and (B) in the absence of FDP. PK was purified using standard methods.[11] The inhibition by oxalate was competitive with respect to PEP in the presence of FDP and noncompetitive in its absence.

and without the addition of 2 mmol/L oxalate. The possible limiting effect of phosphate and of NAD^+ was investigated in incubation mixtures to which excess phosphate or pyruvate had been added. The pH and the levels of metabolic intermediates are presented in Table 1. Figure 5 represents a "cross-over" plot[15] based on these data. In a similar short-term incubation experiment malonate failed to exert any effect on the level of 2,3-DPG.

The effect of oxalate on red cell survival. Twenty milliliters of rabbit blood was collected into 2.8 mL of CPD solution and divided into bags to which no oxalate was added and those to which sufficient potassium oxalate was added to provide a final concentration of 500 μmol/L. At the end of 21 days storage the survival of the red cells of one of the samples was measured in a normal recipient rabbit, and at the end of 22 days the other sample was labeled with a larger amount of ^{51}Cr and viability again determined in a rabbit. The order of presentation was varied so that two of the rabbits received red cells that had been stored with oxalate on day 21 and the other two those that had been stored with oxalate on day 22. The results of these studies are presented in Table 2. Shown also is the effect of storage of rabbit blood on red cell ATP and 2,3-DPG levels. Oxalate exerted the same favorable effect on 2,3-DPG concentrations and unfavorable effect on ATP concentration of rabbit erythrocytes as were observed with human cells.

DISCUSSION

Although oxalate has long been used as an anticoagulant for the collection of blood for diagnostic studies, no thought has apparently been given to its use for blood storage. This has probably been due to the presumed toxicity of oxalate. However, the concentration of oxalate required to aid in the maintenance of red cell 2,3-DPG levels is much lower than that required as an anticoagulant. Even a concentration of only 50 μmol/L exerted a substantial favorable affect on red cell 2,3-DPG: after 21 days' storage the levels had declined by only about one-third. Assuming uniform distribution throughout body water, the instant administration of 450 mL of blood containing this concentration of oxalate would result in a rise of only ~0.6 micromolar in the oxalate level, an increase of the order of 20%. One must take into account, of course, the effect of the administration of multiple units of blood, the rate of clearance of oxalate in normal and diseased individuals, and the existence in the population of many individuals who may have hereditary abnormalities in oxalate transport[16] potentially leading to calcium oxalate stone formation.

Table 1. Levels of Metabolic Intermediates in Red Cell Suspensions Incubated With and Without Oxalate and the Indicated Additives

	2.5 mmol/L Phosphate		10 mmol/L Phosphate		2.5 mmol/L Phosphate 10 mmol/L Pyruvate

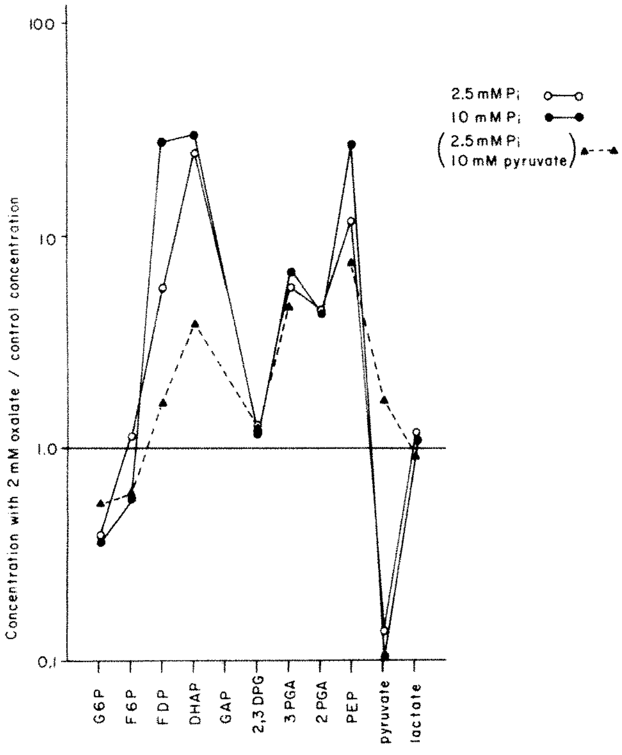

Fig 5. A crossover plot demonstrating the effect of oxalate after six hours' incubation in autologous plasma at 37°C under 95% air-5% CO_2. The effect of added P_i and pyruvate are shown: concentrations represent the amount added to those already present in plasma.

The discovery that oxalate increases the levels of 2,3-DPG in stored blood provides a solution to the problem of why ascorbate appeared to have this effect. We are unable to explain why ascorbate preparations failed, in our earlier studies,[1] to result in enzyme inhibition. It is possible that the preparation used in the enzyme assays was of higher purity than those used in the storage studies. Since these investigations were carried out some 15 years ago, the purity of the various lots used can no longer be determined. Similar differences in purity probably account for the discrepancy between our finding that dehydroascorbate was ineffective[7] while Dawson et al[4] subsequently reported that it was more effective than was ascorbate itself.

Efforts to maintain 2,3-DPG during prolonged blood storage are generally directed at creating appropriate modifications of the metabolic flow within the erythrocyte. Such a modification may consist of providing an additional substrate for red cell metabolism. Dihydroxyacetone and inosine are such substances. Dihydroxyacetone is converted to DHAP by red cell triokinase.[17] Inosine undergoes phosphorolysis to ribose-1-phosphate and hypoxanthine, and the ribose-1-phosphate is converted in the hexose monophosphate pathway to F-6-P and to GAP.[18] In each of these cases use of the new substrate is less sensitive to a fall in the pH of stored blood than is glucose, providing a distinct metabolic advantage to the stored erythrocytes. An alternative to providing a more efficient substrate is modifying red cell preservatives so as to inhibit or to stimulate reactions that influence 2,3-DPG synthesis or degradation. In the past, manipulations of hydrogen ion, pyruvate, and phosphate concentrations have been used for this purpose.[19] Increasing the pH stimulates the diphosphoglycerate mutase (DPGM) and inhibits the DPGP reactions.[20] Pyruvate serves to oxidize NADH to NAD, thereby increasing the level of one of the required co-factors for the glyceraldehyde phosphate dehydrogenase (GAPD) reaction.[21,22] The product of this reaction, 1,3-DPG is the immediate substrate for the formation of 2,3-DPG. Phosphate stimulates glycolysis, probably largely by relieving the inhibition of hexokinase by G-6-P.[23]

Table 2. The Effect of Oxalate on the Storage of Rabbit Blood

	ATP (μmol/g Hb)		2,3-DPG (μmol/g Hb)		Viability (%)
Storage Medium	Day 0	Day 21	Day 0	Day 21	Days 21-22
CPD*	7.34	1.76	28.65	13.12	71.2, 68.8, 65.6, 64.4
CPD + oxalate	7.34	0.72	28.65	28.12	72.6, 78.5, 66.8, 69.6

*The same animals served as controls in a concurrent investigation of BW440C.[12]

It is the DPGM and DPGP reactions that directly control the level of 2,3-DPG in erythrocytes, but these reactions, in turn, are influenced by other metabolic changes in the erythrocyte. PK deficiency is associated classically with increased 2,3-DPG levels, sometimes even in the heterozygous state.[24] The effect of PK deficiency is presumably due to the accumulation of substrates proximal to the PK reaction, ie, PEP, 2-PGA, and 3-PGA. The latter compound inhibits DPGP and stimulates DPGM. Vora recently suggested that inhibitors of this reaction might be useful in maintaining 2,3-DPG levels during blood storage.[25]

In the present investigation we extended the observations of Kandler et al.[9] Red cell membranes are readily permeable to the oxalate anion,[26] even at 0°C.[16] Oxalate increases 2,3-DPG levels not only in blood stored in an artificial additive solution, but also in CPD anticoagulant. Although ATP depletion accompanied the improved 2,3-DPG maintenance, red cell viability was not impaired, at least in rabbits. Oxalate did not exert its effect by altering intracellular pH. It is a known inhibitor of both plasma LDH[27] and of L type (red cell) PK.[28] We found that not only these enzymes but also red cell monophosphoglycerate mutase is inhibited by oxalate. Our kinetic studies indicated that the inhibition of PK is competitive with respect to PEP when the allosteric effector, FDP is present, a finding that is consistent with data obtained earlier in the study of L type PK.[28]

At 37°C oxalate increases the 2,3-DPG levels of red cells incubated in their own plasma even for a few hours. This provided us with the opportunity of addressing the question of how oxalate accomplishes its effect on 2,3-DPG levels. The studies in whole red cells pin-point the major functional lesion induced by oxalate to the PK reaction: the cross-over plot (Fig 5) shows that the concentration of intermediate compounds proximal to the PK reaction is increased and that those distal to the reaction are decreased. However, a second cross-over was also present at the GAPD step. A deficiency of either phosphate or NAD could produce such an effect. The cross-over before GAPD is not eliminated by increasing the phosphate concentration by 7.5 mmol/L. However, increasing the available NAD by the addition of pyruvate[21,22] greatly decreased the accumulation of substrates proximal to the GAPD reaction. Thus, it appears that in addition to its effect on the PK reaction, oxalate produces a change in the NADH/NAD ratio of red cells, possibly merely by inhibiting the LDH reaction.

Although the potential toxicity of oxalate might preclude its clinical use, its effect suggests that other PK inhibitors might be useful, if one that was sufficiently nontoxic could be found. It is of interest, in this respect that malonate, the structure of which superficially resembles PEP more closely than does that of oxalate, has no effect on either the PK reaction or on 2,3-DPG levels in incubated red cell suspension. Oxalate is a normal plasma constituent, circulating at a level of ~4 μmol/L.[29,30] It may be that this compound may exert some in vivo regulatory effect, and further studies are underway to explore this possibility.

Intensive Chemotherapy in Aggressive Lymphomas: Updated Results of LNH-80 Protocol and Prognostic Factors Affecting Response and Survival

By Bertrand Coiffier, Paul-André Bryon, Martine Ffrench, Michel Blanc, Catherine Sebban,
Françoise Berger, and Jean-Jacques Viala

One hundred patients with aggressive malignant lymphomas treated with the LNH-80 regimen were evaluated for long-term survival and pretreatment characteristics predictive of response and survival. LNH-80 consists of three intensive courses of adriamycin cyclophosphamide viudesine bleomycin (ACVB) followed by sequential consolidation and final intensification. Eighty-four patients went into complete remission (CR), eight had a partial response (PR), three failed to respond, and five died during induction. Twenty-three patients (27%) relapsed, in two of whom a prolonged second remission was obtained. Sixty-three patients are currently alive, two of them with disease. Four patients died in CR. Median survival and median freedom from relapse survival were not reached with a median follow-up of 4½ years. Characteristics negatively associated with response in multivariate analysis were: poor performance status, bone marrow involvement, and two or more extranodal sites of disease. Duration of CR was associated with splenic involvement. Three characteristics were negatively associated with survival in multivariate analysis: age, high grade subtypes, and bone marrow involvement.

© 1987 by Grune & Stratton, Inc.

THE POOR PROGNOSIS associated with aggressive lymphomas has been dramatically improved by intensive combination chemotherapy. Regimens such as M-BACOD,[1] ProMACE-MOPP,[2] MACOP-B,[3] and LNH-80[4] have been associated with increases of 10% to 30% in complete remission (CR) rates over those attained by CHOP regimens,[5,8] and a concurrent decrease in relapse rates. Thus a greater number of patients survive 3 years of more. However, the long-term results of these intensive regimens are not known and their superiority is not definitively accepted. Multicenter randomized studies are currently in progress in the United States and Europe to verify the better results of intensive regimens over those obtained with CHOP regimens. Even with these newer regimens, there are some patients who fail to respond or who relapse prematurely. Prognostic factors have been identified in patients treated with CHOP[5,9] or newer[10] regimens. This report updates the results of the LNH-80 regimen on 100 patients, with a median follow-up of 4½ years. Results already reported after 2 years of follow-up[4] have been maintained with a plateau over 60%. Factors associated with response and/or survival are specified.

PATIENTS AND METHODS

Patients. One hundred patients with aggressive malignant lymphoma (ML) were treated with the LNH-80 regimen: the 97 patients previously described[4] and three additional patients who had been excluded from the first publication due to the long time interval between diagnosis and treatment. Since they did not receive any chemotherapy or radiotherapy during this interval, they were brought into this study. All the patients were treated in our department between March 1980 and April 1984. All patients had given their informed consent in accordance with local institution guidelines. Entrance criteria for the protocol have been previously described[4]: diagnosis of aggressive ML according to the Working Formulation,[11,12] stage II or greater for intermediate grade ML, all stages for high grade ML, age <75 years, no contraindication to adriamycin, no previous chemotherapy or radiotherapy.

Of the 100 patients, 69 were males and 31 were females. Median age was 48.5 years (range 11 to 73 years, with three patients <15 and eight patients >65 years). Initial staging procedures included chest radiography, bone marrow aspiration and biopsy, liver function tests, CSF examination, abdominal echography and/or computed tomography (CT). Other examinations were performed as clinically indicated. The clinical presentation was detailed in the earlier report.[4] Briefly, 66 patients had stage IV disease, 48 had B symptoms, 46 a performance status >1, 65 a large tumoral mass, 21 one extranodal site. Lactate dehydrogenase (LDH) was ≥ 2.5 times the normal level in 29 patients. Bone marrow involvement was present in 34 patients. Morphological subtypes are listed in Table 1.

Treatment. The LNH-80 regimen shown in Fig 1 included three phases of chemotherapy. The induction phase consisted of three courses of ACVB. A fourth course was administered if CR had not been obtained after three courses. The courses were initiated every 15 days or when polymorphonuclears increased to $>1{,}500 \times 10^9$/L. A consolidation phase of sequential chemotherapy was initiated 1 month after the last ACVB. A final intensification was started 2 months later with two courses of AraCVmB. CNS radiotherapy was administered in cases of initial CNS localization.

Prognostic factors. The factors evaluated for potential prognostic significance included sex, age, performance status, presence of B symptoms, morphologic subtype, immunologic phenotype, sites of involvement. number of extranodal sites of disease, bulky (more than 7 cm in diameter) tumor, serum LDH, alkaline phosphatase and protein levels, complete blood count, and intensity of administered drugs during the induction phase. Performance status was based on the Eastern Cooperative Oncology Group scale: 0 to 4. Pathologic review was done by two hematopathologists (PAB and FB) according to the Working Formulation.[11,12] Immunologic phenotypes were determined in 37 patients by light chain characterization or monoclonal antibody typing,[13] either on cell suspensions or on frozen specimens. LDH levels were expressed as multiples of the maximum normal value. Intensity of administered drugs during the induction phase was calculated as the number of milligrams per

Table 1. Results of Treating 100 Patients With the LNH-80 Regimen, According to Histologic Subtypes Defined in the Working Formulation

Histologic Subtypes	N	CR	Relapse	Percent Surviving at 5 y ± SE	No. at Risk
Intermediate grade (%)	47	38 (81)	9 (24)	72 ± 7	29
Follicular large cell	3	2	—	66 ± 27	2
Diffuse mixed	26	21	4	68 ± 9	14
Diffuse large cell	18	15	5	74 ± 10	14
High grade (%)	48	41 (85)	13 (32)	52 ± 7	21
Immunoblastic	23	19	5	46 ± 11	8
Lymphoblastic	6	6	2	67 ± 19	4
Small noncleaved	19	16	6	53 ± 11	10
Histiocytic	2	2	—	100	2
Unclassifiable	3	3	2	33 ± 27	1
Total (%)	100	84 (84)	23 (29)	61 ± 5	45

There is no statistical difference between intermediate and high-grade lymphomas for response and relapse rates ($P > .10$) and for survival duration ($P > .05$).

square meter of cyclophosphamide and adriamycin per 15 days and expressed as a percentage of the theoretical dose.[14]

Assessment of response. Response to treatment was assessed at the start of the consolidation phase. CR was defined by the disappearance of all clinical evidence of disease and the normalization of all laboratory values. Some patients with persisting radiographic abnormalities were deemed to be in CR if morphologic examination did not reveal any evidence of lymphoma: these patients were considered to have a persisting necrotic mass.[15] Partial response (PR) was defined as >50% reduction in the largest dimension of each site of measurable disease. The failure category comprised progressive disease, transient disease regression, or death during the induction phase.

Statistical methods. Duration of remission was calculated from the onset of the consolidation phase to the first objective evidence of relapse. Survival duration was calculated from the beginning of treatment until death. Survival curves were estimated by the method of Kaplan and Meier.[16] Univariate analyses were performed using the χ^2 and log-rank tests.[17] Any factor significant at the 0.10 level was included in a logistic regression analysis of response[18] and in a proportional hazards model regression analysis of survival[19] using the BMDP package (Statistical Sofware, Los Angeles).

RESULTS

Eighty-four patients (84%) achieved CR. Five patients (5%) died during the induction phase, eight patients (8%) presented a PR, and three patients (3%) failed to respond. Two of the eight PR patients were alive at 2 years, but none were alive at 4 years. Of the 84 CR patients, 23 (27%) relapsed 5 to 56 months after diagnosis. Only six of the patients relapsed after 18 months, and two more of them relapsed after 3 years. CNS relapse was observed in two of the ten patients with initial CNS localization, but in none of the others. Results according to histologic subtype and immunologic phenotype are presented in Tables 1 and 2. Nineteen of the 23 patients who relapsed were rebiopsed: A histologic progression was seen in five patients and a follicular pattern was seen in two.

Fig 1. Scheme of the LNH-80 regimen.

Sixty-three patients (63%) are currently alive, two with disease and two in a stable second CR of >3 years. Four patients died in CR: one case each of CMV encephalitis, interstitial pneumonia, staphylococcus septicemia, and acute myeloblastic leukemia (18 months after diagnosis). Overall treatment mortality rate was 9% (five patients during induction and four in CR). Overall survival and freedom from relapse (FFR) survival are presented in Fig 2. Median survival and median FFR survival were not reached with a median follow-up of 4½ years.

Prognostic indicators of response to chemotherapy. Forty-five clinical or biological factors determined at diagnosis were evaluated individually as possible prognostic indicators of response to therapy. The response rates associated with some of these factors are shown in Table 3. Statistically significant ($P < .05$) factors negatively associated with response were age >50 years, poor performance status, bulky tumor, two or more extranodal sites of involvement, bone marrow, hepatic, splenic, or pleural involvement, hemoglobin <100 g/L and LDH >2.5 times the normal level.

Single factors not predictive of response to therapy

Table 2. Results According to Immunologic Phenotypes of the 37 Phenotype Patients Treated With the LNH-80 Regimen

Immunologic Phenotype	N	CR	Relapse	Percent Surviving at 5 y ± SE	No. at Risk
B cell	24	20	9	61 ± 10	10
Peripheral T cell	13	9	2	35 ± 14	3

There is no statistical difference in response and relapse rates between B cell and peripheral T cell lymphomas. There is a borderline significant difference for overall survival (Mantel-Cox-Savage test: $P = .05$).

included sex, morphologic subtype, immunologic phenotype, stage, B symptoms; digestive, head and neck, cutaneous, pulmonary, pericardiac, osseus, or neurologic localization; presence of a large mediastinal or abdominal mass; decreased level of proteins, albumin, gammaglobulins, platelets, or polymorphonuclear leukocytes; increased level of gammaglobulins, lymphocytes, lymphoblasts, or creatinine; accelerated sedimentation rate, and drug intensity of induction chemotherapy.

The factors associated with response according to univariate unadjusted analysis were further examined by multivariate logistic regression analysis. All the factors having prognostic significance were known for all the patients except the LDH level for five patients. Two studies were performed: the first on 95 patients with all the factors, the second on all the patients without the LDH level. The two studies gave the same results: poor performance status, bone marrow involvement, and two or more extranodal sites remained statistically significant ($P < .05$).

None of the factors studied was statistically associated with relapse in univariate or multivariate analyses. Drug intensity during the induction phase had borderline significance ($P = .07$). The presence of a residual necrotic mass in 16 patients was not associated with a greater risk of relapse ($P = .15$).

Prognostic indicators of survival. The clinical and biological factors examined for their value in predicting response were also assessed for their relation to survival (Table 4). Single factors statistically associated with short survival were bone marrow involvement ($P < .01$) (Fig 3), LDH >2.5 times the normal level ($P = .02$), age >50 years ($P = .02$), hemoglobin level <100 g/L ($P = .03$), and more than one extranodal site ($P = .05$). Poor performance status and peripheral T cell phenotype had borderline significance: P value < 0.05 in the Wilcoxon test, and <0.10 in the Mantel-Cox-Savage test. None of the other factors tested was statistically associated with poor survival, particularly age, morphologic subtype, stage, B symptoms, hepatic, splenic, digestive, or neurologic localization, and drug intensity during the induction phase.

All the factors with some significance were included in a multivariate Cox regression analysis without the stepwise selection (Table 5). The analysis was performed on two sets of patients: all 100 patients, and the 95 for whom LDH was known. Factors found to be significantly associated with poor survival were increasing age, high grade subtypes, and bone marrow involvement.

The prognostic score described by Shipp et al[10] in their study with the M/m-BACOD regimens was applied to our patients. This score was based on the performance status, the diameter of the largest mass, and the number of extranodal sites of disease; it divided patients into three subgroups with a predicted 5-year survival rate of 68%, 55%, and 24%. Figure 4 shows the Kaplan-Meier survival curves for our

patients divided into Shipp's risk groups. We obtained predicted 5-year survival rates of 78%, 71%, and 51% (Table 4). The score was a statistically significant indicator of prognosis: *P* value < 0.05 for response and survival. In multivariate analyses, the score did not remain a significant predictor of the probability of response, relapse or death.

DISCUSSION

Sixty-four patients (64%) with aggressive ML treated by the LNH-80 regimen are alive, 61 of them in persistent CR with a median follow-up of 4½ years. These results are superior to those obtained with CHOP and CHOP-like regimens.[5-8] A large proportion of patients will probably be cured, but 3 to 5 more years are required before the results can be considered definitve. These results are the best reported with a follow-up >3 years: the M/m-BACOD regimens have achieved a median survival of 68 months with a 5-year survival rate of 50% for large cell ML[10]; the ProMACE-MOPP/CytaBOM regimens and the MACOP-B regimen have not been updated as yet, but the MACOP-B regimen was reported to give good results only in large cell ML.[20]

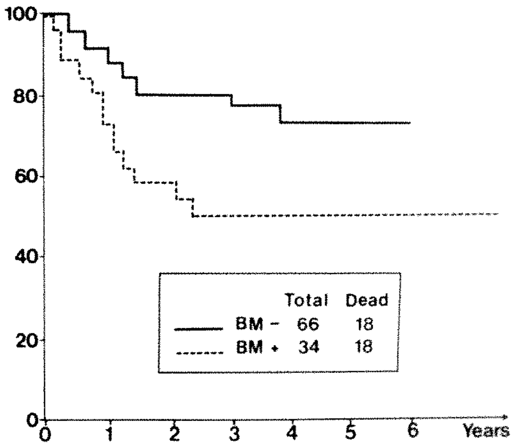

Fig 3. Effect of bone marrow involvement on the survival of patients with aggressive lymphoma treated with the LNH-80 regimen.

Our 100 patients were evaluated for prognostic factors that could be predictive of response and survival. Poor performance status, bone marrow involvement, and two or more extranodal sites of disease were found to be negatively associated with response. Age, high grade subtypes, and bone marrow involvement were adversely associated with survival. Marrow involvement was one of the most important prognostic factors, as had also been reported for the CHOP regimen,[5,7,9,21,22] but not in the M/m-BACOD study.[10]

The prognostic factors we found to be significant had been reported in several previous studies on prognostic factors in ML. Poor performance status and presence of B symptoms had been recorded as indicators of low response rate and/or poor survival.[5,7,9,10,22,23] Age was considered an indicator of poor survival in most of the studies, but the dividing line was variable: 55 years,[22] 55 and 65 years,[23] 60 years.[24] Visceral localizations as liver, spleen, pleura were occasionally asso-

Table 5. Multivariate Proportional Hazards Regression Analysis of Survival of Patients Treated With the LNH-80 Regimen

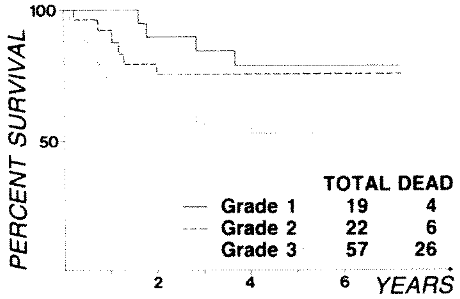

Fig 4. Survival of patients with aggressive lymphoma treated with the LNH-80 regimen according to the score described by MA Shipp based on patients treated with M/m-BACOD regimens.[10]

ciated with response or survival, as was increased LDH level and anemia.[7,9,23] There was some discrepancy concerning the value of morphologic subtype as prognostic indicator,[5,7,9,10,23,24] and most studies did not include patients with high-grade ML. With newer regimens additional prognostic indicators were recognized, such as large tumoral mass (abdominal or not) and the number of extranodal sites of disease.[10] A major difference compared with the results obtained by the M/m-BACOD regimens was that bulky tumor was of little consequence in our series. Only the presence of two or more large tumor masses was associated with poor prognosis and disappeared in multivariate analyses. In contrast with earlier studies that suggested an adverse association between prognosis and specific sites of disease[5,9] such as gastrointestional (GI) tract, spleen, or CNS, our results and those of Shipp et al[10] suggest that it is not the location of the disease that is significant but rather the number of sites.

Although the score described by Shipp was found to have some prognostic significance, the tumoral mass and the number of extranodal sites of disease were not the most significant prognostic factors in our study. While our patients had more indices of poor prognosis, their predicted 5-year survival rates were higher than Shipp's, with a small difference for the best prognostic group (77% *v* 68%), but a large difference for the poor risk patients (52% *v* 24%). This would appear to reflect the better results with our regimen than with the M/m-BACOD, but the actual difference, if any, could only be proved by a randomized study.

Drug intensity during the induction phase[14] was of borderline significance for predicting CR duration. It seems to us that drug intensity in our regimen is one of the factors responsible for the better results obtained, but it is difficult to demonstrate due to its low variation in our patients: those who received 75% of the theoretical dose received more adriamycin or cyclophosphamide per month than in CHOP or M/m-BACOD regimens.

The prognostic significance of the immunologic phenotype had rarely been addressed, probably because peripheral T cell lymphomas were rarely recognized in the past. Whether peripheral T lymphomas have the worst prognosis has been much debated and no firm conclusions can been drawn from the literature. Immunological phenotype is not correlated with other prognostic factors. The poor prognosis of our peripheral T cell lymphoma patients was essentially due to the large number of patients who died in induction, failed to respond, and relapsed during the first months of CR: median survival was only 14 months. The intensive regimen did, nevertheless, yield the best survival rates for peripheral T cell lymphomas compared with other forms of treatment.[25]

The LNH-80 regimen applied to 100 patients with aggressive ML can be credited with keeping 63 of them alive with a median follow-up of 4½ years. These results are the best published so far for this disease. Our results are currently being tested in a multicenter randomized study of the LNH-84 protocol in France and Belgium. More than 750 patients have already been included and the initial results will soon be communicated.

ACKNOWLEDGMENT

We thank P. Adeleine for his helpful statistical advice and all the physicians who have referred their patients to us.

Minimally Differentiated Acute Nonlymphocytic Leukemia: A Distinct Entity

By Edward J. Lee, Avrom Pollak, Richard D. Leavitt, Joseph R. Testa, and Charles A. Schiffer

Ten of 136 consecutive adult patients with previously untreated acute leukemia had morphologically undifferentiated leukemia by light microscopy. Leukemic cells from these patients were characterized by agranular cytoplasm, negative histochemical staining with sudan black (SB) and nonspecific esterase, and absent lymphoid cell surface markers and therefore were not classifiable according to the French-American-British (FAB) system. Electron microscopy with myeloperoxidase (MPO) staining revealed the presence of peroxidase positive cytoplasmic granules and endoplasmic reticulum in eight of the nine patients studied. Cells from the patient who was negative for MPO were also negative for platelet peroxidase. A series of monoclonal antibodies to myeloid antigens also revealed myeloid features with all patients having at least one myeloid differentiation antigen present on the surface of their cells. Common acute lymphoblastic leukemia (ALL) antigen was absent in the nine patients tested. Cytogenetic analysis of blast cells was abnormal in seven patients on whom adequately banded chromosomes were obtained although there were no consistent abnormalities. No patient had a Ph^1 chromosome. Only two of the ten patients achieved a complete remission. Morphologically undifferentiated leukemia may have myeloid features when studied by transmission electron microscopy or with monoclonal antibodies for cell surface markers. Such studies should be performed when the leukemia cannot be classified using either light microscopy or lymphoid cell surface markers. Such patients infrequently achieve remission with standard therapy and constitute a distinct entity.
© 1987 by Grune & Stratton, Inc.

THE DISTINCTION between acute lymphoblastic leukemia (ALL) and acute nonlymphocytic leukemia (ANLL) can usually be made on the basis of light microscopy, polychrome stains, and cytochemical stains such as myeloperoxidase (MPO), sudan black (SB), and periodic acid Schiff (PAS). This distinction is important because of the differences between ALL and ANLL in the choice of chemotherapeutic agents, length of therapy, and propensity of ALL to involve the CNS. The biological basis for this distinction is the presumed origin of the leukemia from the malignant transformation of a stem cell that has undergone limited differentiation. The French-American-British Cooperative Group (FAB) has published standardized critieria by which ALL can be distinguished from ANLL and then further classified into subtypes.[1,2] ALL is defined as a leukemia in which the majority of cells have scant amounts of agranular cytoplasm, predominantly round nuclei, and homogeneous, slightly condensed chromatin without prominent nucleoli (L1 subtype). The leukemic cells can also be large, with abundant vacuolated basophilic cytoplasm, and prominent nucleoli (L3 subtype). Both of these variants can be readily distinguished from ANLL in Romanowsky polychrome stained preparations. A third subtype of ALL is characterized by large cells that exhibit some heterogeneity in size and have irregular nuclear shape with one or more large nucleoli (L2 subtype). Although blasts from patients with ANLL often contain cytoplasmic granules and thus can be easily distinguished from ALL, some have only small numbers of granules. Such patients with ANLL can then be best distinguished from L2 by cytochemical staining. Using arbitrary criteria, the FAB group states that the presence of <3% MPO positive cells suggests the diagnosis of ALL, whereas, if ≥3% of cells are positive, the diagnosis is ANLL.

In this report we present the results of studies of leukemic cells of ten patients with acute leukemia who did not meet these FAB criteria for ANLL. These patients had leukemic cells that were small, with scant agranular cytoplasm and distinct nucleoli. Auer rods were not seen and cytochemical stains (PAS, SB, chloroacetate esterase, α-Naphthyl butyrate esterase) were negative. The leukemic cells from these patients were studied by ultrastructure and for cell surface markers using monoclonal antibodies. Our data suggest that such undifferentiated leukemias frequently exhibit features that suggest a myeloid origin. Furthermore, our results suggest that these patients infrequently achieve remission when treated with conventional therapy for ANLL.

MATERIALS AND METHODS

Leukemic cells obtained from peripheral blood or bone marrow from 136 consecutive patients (Table 1) referred to the University of Maryland Cancer Center with previously untreated acute leukemia were analyzed. Thirteen patients (eight ALL, five ANLL) had inaspirable marrows at the time of diagnosis, and laboratory studies were performed on peripheral blood or cells obtained from a bone marrow biopsy core. Whenever possible, all of the following series of studies were performed.

Light microscopy. Bone marrow smears (or touch preparations from biopsy cores) and peripheral blood smears were stained with Wright-Giemsa for cell morphology and differential, with histochemical stains including SB, PAS, chloroacetate esterase, and alpha-naphthyl butyrate esterase. Terminal deoxynucleotidyl transferase (Tdt) was detected by indirect immunofluorescence (Bethesda Research Laboratory Inc, Gaithersburg, MD) using the method of Bollum.[3]

Immunologic cell surface marker studies. Cell surface marker studies using a variety of monoclonal antibodies and indirect immunofluorescence microscopy were done using standard methods described elsewhere.[4] Monoclonal antibodies were used to identify

differentiation antigens of T lymphocytes, B lymphocytes, monocytes and granulocytes, as well as to identify the presence and nature of surface or cytoplasmic immunoglobulins. An antigen was considered present if >20% of cells studied were positive.

Ultrastructural studies. Bone marrow particles were fixed in a phosphate-buffered formaldehyde-glutaraldehyde mixture and further processed for transmission electron microscopy (TEM) in a routine fashion. For the ultrastructural localization of platelet-specific peroxidase, the tissue was first fixed in a tannic acid-aldehyde mixture.[5] Thereafter, the material for peroxidase staining was incubated in 3,3′-diaminobenzidine (DAB) medium, fixed, embedded, and sectioned.

Cytogenetic analyses. Procedures for the cytogenetic analysis of leukemia patients have been described in detail elsewhere.[6] Briefly, marrow cells were examined from 24 hour unsynchronized cultures and methotrexate-synchronized cultures. Chromosomes were examined with conventional Giemsa stain and quinacrine fluorescence banding techniques. All chromosome studies were performed at diagnosis, before initiating therapy. Chromosomes were identified and karyotypes assigned according to the International System for Human Cytogenetic Nomenclature (1985).[7]

Patients were classified by light microscopy according to the criteria of the FAB schema for both ANLL and ALL.[1,2]

RESULTS

Of the 136 patients analyzed, 110 (81%) had ANLL, 16 (12%) had ALL, and ten patients (7%) had leukemia that was not classifiable by conventional morphologic and cytochemical criteria (Table 1). There were no clinical characteristics, abnormalities on physical examination or initial laboratory parameters that distinguished these ten patients. One of these patients (no. 8) developed leukemia after extensive chemotherapy and radiotherapy for Hodgkin's Disease. No history of mutagen exposure was noted in any of the other nine patients. A second patient (no. 6) had a low WBC count for 4 to 5 months before developing leukemia but no other patient had a hematologic disease before the diagnosis of acute leukemia. The results of laboratory investigations on these ten patients are summarized in Tables 2 and 3.

Light microscopy. Marrows were hypercellular in all but one patient. Six patients had only occasional cells identifiable that were not leukemic whereas the other four patients had easily identified populations of residual mature myeloid or erythroid cells. In all of these patients, the leukemic cells were small with sparse, agranular, lightly basophilic cytoplasm, round nuclei, immature chromatin and prominent nucleoli (Fig 1). Auer rods were absent. In all

#Myeloperoxidase stain by transmission electron microscopy.

patients, <3% of the blasts were positive with cytochemical staining for SB and staining with specific or nonspecific esterases and PAS was uniformly negative. Thus, although the appearance of the leukemic cells did not suggest lymphoid origin, cytochemical criteria for the suspected diagnosis of ANLL were not met.

Leukemic cells were evaluated for the presence of Tdt by indirect immunofluorescence in all ten patients. In one patient (no. 1), 20% of the blasts were positive and in a second (no. 3), 40% were positive. The other eight patients each had <5% of their leukemic cells stain positively.

Ultrastructural studies. TEM was performed on leukemic cells of nine of the ten patients. Blast cells in all patients appeared extremely undifferentiated on TEM. The nuclei contained primarily euchromatin with little heterochromatin, and large nucleoli were seen. With MPO staining (Fig 2), eight of the nine patients had leukemic cells containing small numbers of MPO positive granules in the cytoplasm in 6% to 40% of the blasts. Other cells had MPO-positive material in endoplasmic reticulum and nuclear membrane. MPO-positive cytoplasmic granules are not found in megakaryocytes or their precursors, or in cells of lymphoid lineage. Except when cells are fixed with tannic acid, the presence of MPO staining in endoplasmic reticulum and nuclear membrane identifies cells of myeloid lineage.[5] Thus, these patients were thought to have leukemia derived from a very early precursor cell committed to myeloid differentiation. Only patient no. 2 had leukemic cells lacking MPO activity, and megakaryocyte-specific peroxidase was also absent from bone marrow and peripheral blood cells examined after tannic acid fixation. Thus, eight of nine patients studied with TEM had evidence suggesting myeloid origin of their leukemic cells.

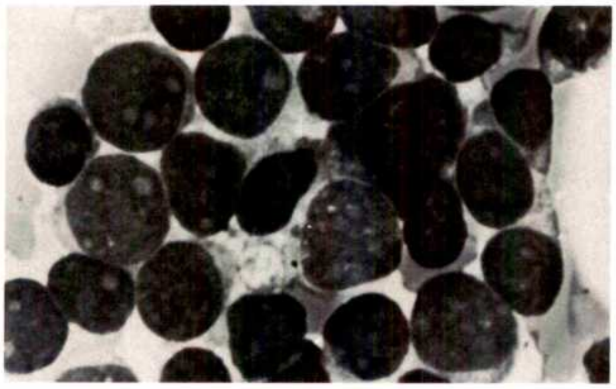

Fig 1. Photomicrograph of Wright-Giemsa stained bone marrow smear from patient no. 6. Several blasts contain scant cytoplasm and prominent, often multiple nucleoli. No Auer rods or cytoplasmic granulation can be identified. (Original magnification ×1,000; current magnification ×400.)

Cell surface markers. Leukemic cells from all ten patients were evaluated for the presence of cell surface antigens with monoclonal antibodies to normal myeloid differentiation antigens.

Myeloid differentiation antigens were present on the leukemic cells of all 10 patients. All but two patients had several such markers identified on their cells (Table 3). No consistent pattern of reactivity was seen although My-10 (seven of eight patients) and My-11 (six of eight) were frequently found.

The common ALL antigen was not detected on the cells in any of the patients. T-cell differentiation antigens were found infrequently. The cells of two patients (no. 4 and 5) had a single such antigen. Leukemic cells from three patients were evaluated for B lymphocyte markers. None of these studies were positive, whereas all specimens tested were positive by HLA-DR (Ia-antigen).

Chromosomal analyses. Cytogenetic analyses were per-

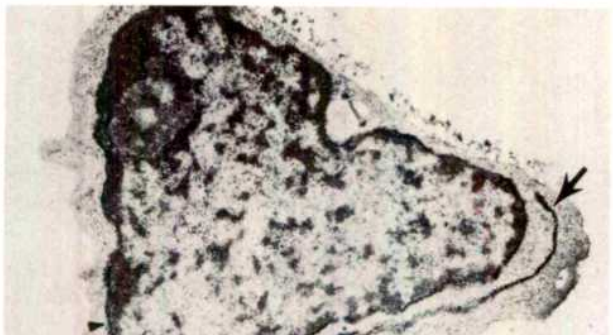

Fig 2. (A) Electron micrograph of a blast cell from patient no. 4 after formaldehyde-glutaraldehyde fixation and MPO staining. The nucleus contains a large nucleolus and little heterochromatin. The nuclear membrane stains positively with MPO (arrowheads). The cytoplasm contains endoplasmic reticulum, which also stains positively for MPO (arrows). (Original magnification ×14,000; current magnification ×11,060.) (B) Electron micrograph of a blast cell from patient no. 6 after formaldehyde-glutaraldehyde fixation and MPO staining. The nucleus contains a large nucleolus and little heterochromatin. The cytoplasm contains mitochondria, endoplasmic reticulum, and MPO positive granules (arrows). (Original magnification ×9,300; current magnification ×7,350.)

formed in all ten patients. No patient had a Ph^1 chromosome. Two patients (no. 1 and 9) had poorly banded chromosomes that precluded detailed analysis. Seven of the eight patients who had adequate metaphases examined had an abnormal karyotype. Two patients (no. 3 and 6) had loss of one no. 7 chromosome, and a third (no. 5) had loss of part of the short arm of one no. 7 chromosome. One no. 17 chromosome was missing in one patient (no. 3), and a second patient (no. 4) had a dic(17) that resulted in loss of part of the short arm of the no. 17 chromosome. Two patients (no. 2 and 7) had translocations involving one no. 1 chromosome but with the involvement of different chromosomes. One of the latter patients (no. 7) also had t(8;14). No other chromosome was involved in more than a single patient. Patient no. 10 had a normal karyotype.

Response to therapy. The ten patients with FAB-unclassifiable acute leukemia all received intensive chemotherapy. Eight patients were treated with daunorubicin (DNR) and cytosine arabinoside (Ara-C) according to the protocol therapy described below for ANLL. Two of these patients also were treated with vincristine and prednisone, one (no. 3) because of the presence of Tdt, and the other (no. 2) because of the absence of platelet or MPO staining on electron microscopy. One of these eight patients achieved a complete remission (CR). Two patients (no. 1 and 4) were treated with a regimen developed for ALL consisting of tandem methotrexate and L-asparaginase in combination with vincristine and dexamethasone.[15] One of these two patients, also with a low number of TdT-positive cells, achieved a CR. Of the eight patients in whom CR was not achieved, one (no. 7) died on day 15 with an aplastic bone marrow, while all seven of the remaining patients had refractory leukemia.

Of the 110 patients with ANLL diagnosed by routine criteria, 104 were evaluable for response to chemotherapy. Five patients who were not treated and one who was lost to follow-up were inevaluable. Of these 104 patients, 57 of 90 (63%) with de novo ANLL achieved CR (Table 1). Five of 14 (36%) patients with secondary ANLL achieved CR. Treatment of these 104 patients consisted of protocol chemotherapy (99 patients) with DNR 45 mg/m^2 daily for three days, and Ara-C by continuous infusion for seven days at a dosage of either 100 mg/m^2 before December 1982[16] or 200 mg/m^2 after January 1983.[17] Five patients who received other regimens did not achieve a complete response.

Of the 16 patients with ALL, eight of 15 achieved CR after treatment with either DNR, vincristine, prednisone, and L-asparaginase[18] or with a combination of methotrexate and L-asparaginase given in a tandem fashion with vincristine and dexamethasone.[16] One patient refused treatment.

DISCUSSION

The ten patients described here did not meet the FAB criteria for any of the various subtypes of acute leukemia. The diagnosis of ANLL could be made only by ultrastructural MPO staining or cell surface marker studies. Eight of the patients (no. 1, 3, 4, 5, 6, 7, 9, and 10) had MPO positive cells and, on this basis, had ANLL. The FAB group suggests that the demonstration of MPO positive blast cells by TEM is sufficient to establish myeloid lineage.[2] The number of cells with MPO positive material varied considerably, from 6 to 40%, in different patients. It is likely that this underestimates the frequency of positive cells because the thin sections necessary for TEM may by chance not detect the presence of small granules. With MPO at the light microscopy level, an arbitrary minimum percentage of 3% has been set by the FAB group; no such "definition" exists for ultrastructural MPO. The variation in both the percentage of positive cells and the degree of "positivity" per cell emphasizes the considerable heterogeneity of morphologic differentiation occurring even within the same patient.

In the other two patients, the diagnosis of ANLL depended solely on cell surface marker studies. All ten patients tested positively for myeloid antigens, and in two patients (no. 2 and 8), this was the only evidence of lineage specificity. When MPO or platelet PO activity is absent (patient no. 2) or cannot be established (patient no. 8), the constellation of four different positive "myeloid" monoclonal antibodies as for patient no. 2, and five different positive "myeloid" monoclonal antibodies, as for patient no. 8, is sufficient to indicate myeloid features and to confirm the diagnosis of ANLL. This is substantiated by the presence of OKM-1 in both patients no. 2 and 8. A recent review notes that OKM-1 has not been reported in cells from any of 92 patients with lymphoid leukemias.[19] Other monoclonals positive on cells from these two patients are less lineage-specific. My-10 and My-11 have been identified on both ALL and ANLL.[9] The absence of Tdt and CALLA in these two patients in conjunction with several positive myeloid antigens confirms the presence of a very early cell committed to myeloid differentiation.

There have been a number of descriptions of patients with characteristics suggestive of both ALL and ANLL, examples of so-called "lineage infidelity" or biophenotypic leukemia.[20-22] Four of our patients may fit into this category. Two patients (no. 1 and 3) had Tdt detected in a minority of their blasts. Tdt positivity was detected in 19 of the 110 (17%) patients with classifiable ANLL in our study. Some may have been due to nonspecific Fc receptor mediated binding of reagents in that they were less positive after incubation of cells in AB plasma. Others, however, seemed to represent "true" positives. The presence of Tdt in some patients with ANLL has been confirmed by other investigators using a biochemical method[21] of identifying Tdt activity, and has recently been identified in as many as 22% of patients with ANLL using an immunoperoxidase method.[23] Tdt has also been detected in immature cells in regenerating bone marrow[24] and in a recent review by Ben-Bassat and Gale,[25] it was stated that Tdt positivity alone in association with myeloid characteristics is insufficient to confirm the suspicion of biophenotypic leukemia.

Similarly, antibodies raised against thymic cells (OKT-6 and OKT-10), were reactive in two MPO positive, TdT negative patients (no. 4 and 5). Reinherz et al[26] found that the spectrum of OKT-10 positive cells included up to 20% of cells in normal bone marrow, suggesting that the determinant recognized by this antibody is not restricted to lymphocytes, and represents an "early differentiation antigen." Similarly, OKT-6 has been reported to be reactive with malignant cells from patients with histiocytosis X,[27] and with the myeloid cell line HL-60 after stimulation with gamma interferon.[28] Neither patient was studied for the presence of T-cell receptor gene rearrangements.

The diagnosis of acute megakaryoblastic leukemia (FAB-M7) was considered and excluded in nine of the ten patients. In immature megakaryoctyes, the peroxidase stain is positive only after fixation in tannic acid, and peroxidase-positive material is present in the nuclear membrane and endoplasmic reticulum.[5] Two patients with the M7 subtype were identified within the group of 110 with ANLL using this technique. One of the ten patients studied had neither MPO nor megakaryocyte peroxidase positive cells in either peripheral blood or bone marrow. Eight patients had MPO positivity on TEM with standard fixation, a finding not found with M7 leukemia. The FAB-M7 subtype was therefore definitively excluded in these nine patients.

These patients thus had leukemia that lacked features that are currently recognized as diagnostic of ALL or ANLL within the FAB schema. The FAB group recognizes that unclassifiable leukemias occur, but estimates the frequency at 2% in adults.[2] They describe this group as a mixture of patients with basophilic leukemia, hypoplastic ANLL, and ANLL requiring ultrastructural peroxidase studies "to confirm their granulocytic nature." In our series, ten of 136 patients (7%) fit this last category. In a series of patients reported by Youness et al,[29] 22 of 225 patients (10%) were thought to have acute undifferentiated leukemia (AUL), defined by the investigators as patients in whom light microscopy with the usual battery of cytochemical stains was not helpful in classification in the FAB schema. As in our patients, the leukemic cells were described as undifferentiated agranular cells with more cytoplasm than an L1 blast, round nuclei and one to two nucleoli. Of these 22 patients, 14 were classified as ANLL on the basis of TEM and MPO staining. In a third series, four of 56 (7%) ANLL patients were classified as AUL, but were defined only as "unclassifiable."[30] A fourth series described nine of 202 (4%) with either AUL or "biphenotypic" leukemia with leukemic cells similar to those described in our patients.[31] Despite the lack of uniform definition, all these series identify patients who had undifferentiated leukemia that was nonetheless considered myeloid by varying criteria. This subtype occurs with a frequency similar to that of the M3, M6, or M7 subtypes suggesting that the FAB group has underestimated the frequency of the entity of minimally differentiated acute myeloid leukemia.

Some patients with minimally differentiated ANLL may have been classified as ALL in many centers. A recent report from Cancer and Leukemia Group B (CALGB) of 129 adult patients treated for ALL identified four patients (3%) who lacked both B cell and T cell markers.[22] These patients exhibited only myeloid differentiation antigens when studied with monoclonal antibodies. A French group reported 25 adult patients with "ALL" who lacked both B cell and T cell markers.[32] Five patients studied by TEM with peroxidase staining demonstrated myeloid blasts.

No consistent cytogenetic abnormality was identified in the group of patients with minimally differentiated ANLL, but the number of patients is small. Seven patients with adequate mitoses for detailed analysis had structural rearrangements. One of these alterations (patient no 7), t(8;14) (q24;q32), is typically found in Burkitt's lymphoma and ALL-L3. Surface immunoglobulin was not evaluated in cells from this patient, although ultrastructural MPO was positive. Many of the other chromosome changes (eg, +7,+8, dic(17), and ring chromosomes) have been reported both in ANLL and ALL. Four of the seven patients had complex karyotypes similar to those in ANLL patients described by Sakurai and Sandberg[33] as "major karyotypic abnormalities" (MAKA). Among the remaining three patients, two had ring chromosomes, also a common finding in patients with MAKA. Although one patient (no. 8) with a ring chromosome had a history of prior therapy for Hodgkin's disease and was thought to have a therapy related acute leukemia, the other patients had no history of prior hematologic disease, malignancies, or mutagen exposure. In reviewing the previous mentioned series, only one (Youness et al)[29] examined karyotypes, and the vast majority of cases were examined without the benefit of banding techniques. In the three patients studied with banding, one had a MAKA, a second had two abnormal clones identified, both with different abnormalities of chromosome no. 13, and the third had an abnormality of chromosome no. 21.

Last, the response rate in these ten patients was extremely poor. Treatment in eight patients with standard ANLL chemotherapy produced one brief CR lasting 5 months and six patients had resistant leukemia. The other patient who achieved CR, the eldest of the group, was treated with a regimen active in both ALL and ANLL, and died of complications of further chemotherapy 4 months after achieving CR. These results differ significantly from the 60% CR in the 104 concurrently treated patients with ANLL who were classifiable according to the FAB system ($P = .02$, Fisher exact test). Youness et al found a CR rate of 68% in the 22 patients reported, but the median survival time was only 26.7 weeks.[29] This is considerably shorter than the median survival for patients with ANLL treated at the same institution.[34] In the four patients described by Foon et al,[30] three achieved complete response but data on survival are not available. Mertlesman et al[31] noted both a decrease in the remission rate and shortened duration of survival and remission in their mixed group classified as AUL although statistical significance is not reached due to small patient numbers. In reviewing their results in patients with minimally differentiated ANLL treated as ALL, Reiffers et al noted that all five patients who were MPO-positive by TEM were among the group of seven patients in whom treatment failed to produce a remission.[32] Lastly, CALGB noted that none of the four patients with what they termed "myeloid" ALL achieved CR when treated with daunorubicin, vincristine, prednisone, and L-asparaginase.[22]

The ten patients described here have leukemia that is nonlymphocytic by morphology, ultrastructure, and cell surface markers. The ability to prospectively identify a group of patients with poor response to chemotherapy suggests that minimally differentiated ANLL is indeed a clinically distinct subtype of acute leukemia. This leukemia is presumably derived from very early committed granulocyte precursors. Our series and those previously cited suggest that an M-O category for ANLL be created and defined by the presence of MPO detectable only on the ultrastructural level. The absence of lymphoid markers and the presence of myeloid differentiation antigens is confirmatory, and identify patients in whom TEM with MPO should be examined. It would appear that the prognosis for patients with minimally differentiated ANLL is poor using standard therapeutic approaches.

Evidence for the Interleukin-2 Dependent Expansion of Leukemic Cells in Adult T Cell Leukemia

By Michiyuki Maeda, Naomichi Arima, Yasuhisa Daitoku, Mari Kashihara, Hiroyuki Okamoto,
Takashi Uchiyama, Kenji Shirono, Masao Matsuoka, Toshio Hattori, Kiyoshi Takatsuki,
Koichi Ikuta, Akira Shimizu, Tasuku Honjo, and Junji Yodoi

Interleukin 2 (IL-2) receptor/Tac antigen is abnormally expressed on cells of patients with adult T cell leukemia (ATL) caused by infection with human T lymphotropic virus type I (HTLV-I). Twenty-five patients with ATL were examined to determine whether their leukemic cells continued to show IL-2–dependent proliferation. In 21 patients, the in vitro proliferation of HTLV-I-infected nonleukemic T cell clones was found to be dependent on IL-2. However, clonality analysis based on T cell receptor gene rearrangement profiles and the site of HTLV-I provirus integration revealed IL-2–dependent growth in leukemic cells in four patients with ATL. These results provide evidence for the IL-2–dependent proliferation of leukemic cells in some ATL patients.

© 1987 by Grune & Stratton, Inc.

ADULT T CELL LEUKEMIA (ATL),[1-4] endemic in southwest Japan, the Caribbean Islands, and Africa, is etiologically associated with human T lymphotropic virus type I (HTLV-I).[5-7] Leukemic cells in ATL consist of monoclonal HTLV-I infected T cells[8] with the surface phenotype of helper T cells,[2,9] and they continuously express an excess number of IL-2 receptors.[10-12] Such constitutive IL-2 receptor production by both HTLV-I and HTLV-II–infected helper T cells has been shown to be induced by the *pX* or *tat* genes of the two viruses.[13,14] In contrast, normal mature T cells transiently express IL-2 receptors when stimulated by antigens or mitogens, resulting in transient IL-2–induced cell proliferation.[15] Since T cell proliferation is regulated by the interaction between IL-2 and IL-2 receptors, the abnormal expression of IL-2 receptors on ATL leukemic cells is thought to be responsible for their unregulated growth.[16] Indeed, using IL-2 as a growth factor, long-term cultures of T cells were established from ATL patients,[17-19] but rarely from HTLV-I noninfected healthy donors. However, analyses of the rearrangement profiles of the T cell receptor gene revealed that most of these ATL-derived T cell lines did not represent major clones of the original ATL leukemic cells.[20] Peripheral leukemic cells from ATL patients did not grow in the presence of IL-2.[20,21] However, we found a chronic ATL patient whose leukemic T cells were able to grow as a permanent cell line in the presence of IL-2. This cell line's rearranged T cell receptor gene profile was identical to that of the patient's peripheral leukemic T cells.[20] We therefore speculated that IL-2 acts as a growth factor for HTLV-I–infected T cells in some stage of ATL development.

We extended our work to search for similar cases and, here we report four patients whose leukemic T cells proliferated in the presence of IL-2.

MATERIALS AND METHODS

Patients. Four male patients were diagnosed as having ATL on the basis of clinical and hematological findings. ATL was further confirmed by the presence of a monoclonal population of HTLV-I–infected T cells, identified by Southern blot hybridization using as a probe cDNA of the U3R portion of the HTLV-I genome. The peripheral blood leukocyte (PBL) count and percentage of atypical lymphocytes were 46,000/μL (67%) in patient no. 1 (55 years), 15,500/μL (55%) in patient no. 2 (66 years), 30,900/μL (47%) in patient no. 3 (42 years), 37,500/μL (53%) in patient no. 4 (35 years). Patients no. 1 and 2 had acute ATL, and patients no. 3 and 4 had chronic ATL.

Cells and cell culture. Mononuclear cells were separated by Ficoll-Hypaque centrifugation (LSM solution, Litton Bionetics, Kensington, MD) from heparinized samples of the patients' peripheral blood. Cells were cultured at an initial cell density of 5 to 10 × 10^5 cells/mL in RPMI 1640 medium supplemented with 2 mmol/L L-glutamine, 100 μg/mL kanamycin and 10% to 20% fetal bovine serum (FBS) (Rehatuin, Armour Pharmaceutical Co, Kankakee, IL) in the presence of crude or recombinant IL-2. Cells were subcultured every three to five days by spliting them at a two to five fold dilution depending on their density. Cells were cultured in 55-mm petri dishes (Falcon) at 37°C in a humidified atmosphere of 5% CO_2 in air.

IL-2 preparation. Conditioned medium containing IL-2 was prepared by culturing mitogen-stimulated peripheral blood lymphocytes and spleen cells as described.[20] Recombinant IL-2 produced in *Escherichia coli* was kindly supplied by Dr Y. Sugino (Takeda Chemical Industries, Osaka, Japan). For T cell growth stimulation crude IL-2 was used at a 25% to 50% (vol/vol) concentration in RPMI 1640 medium, and purified recombinant IL-2 was used at 1 to 5 U/mL (1 U/mL = 7.5 ng/mL).

Southern blot hybridization. High molecular weight DNA was extracted from peripheral blood mononuclear cells of ATL patients and from IL-2–dependent T cell line cells derived therefrom. Procedures for DNA extraction, digestion by restriction enzymes, electrophoresis, blotting to nitrocellulose filter, and hybridization with ^{32}P-labeled molecular probes are described elsewhere.[22] To analyze T cell receptor gene rearrangement, a 2.6 kilobase (kb) *Hind*III fragment, containing the constant region of the human β chain, was

used as the probe.[23] To detect HTLV-I provirus the long terminal repeat (LTR) (*Sma*I-*Sac*I, 456 base pairs [bp]) was used as the probe.[24]

Examination of the cell surface phenotype by monoclonal antibody. The surface phenotypes of fresh and cultured ATL cells were examined by indirect immunofluorescence analysis using OK-series (Becton Dickinson, Oxnard, CA), Leu-series (Ortho Diagnostic Systems, Raritan, NJ) and anti-Tac monoclonal antibodies. Fluorescein-isothiocyanate (FITC)–conjugated goat anti-mouse immunoglobulin (Cappel) was used as the second antibody. The results were expressed based on cluster and differentiation (CD) classification.[25] Fluorescence intensity and the percentage of fluorescence positive cells was examined by an Ortho Spectrum III (Ortho Diagnosis Systems, Sunnyvale, CA) flow cytometer.

RESULTS

IL-2–dependent growth of ATL leukemic T cells. Peripheral blood mononuclear cells from patients no. 1 through 4 were seeded in 10% FBS supplemented RPMI 1640 medium in the presence of either crude or recombinant IL-2. The cells began to grow without a lag phase, and after several weeks showed stable growth that was dependent on exogenous IL-2, though the growth pattern varied among cells from different patients. T cell lines derived from patients no. 1, 2, and 4 have been maintained as leukemic clones in in vitro culture for more than a year. Characterization of these T cell lines was carried out after 3 months in culture. A T cell line derived from patient no. 3 has been maintained as leukemic clones for more than 3 months and the Southern blot hybridization study was carried out after 2 weeks in culture. The growth curves for these four T cell lines are shown in Fig 1.

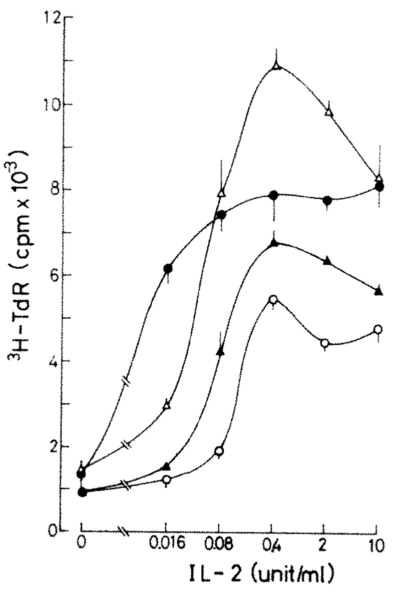

Fig 1. The effect of IL-2 on DNA synthesis in cultured ATL leukemic cells. Leukemic T cells in long-term culture derived from patient no. 1 (●—●), patient no. 2 (O—O), patient no. 3 (▲—▲), and patient no. 4 (△—△), were cultured in the presence of different concentration of purified recombinant IL-2 in 96-well microtiter plate and cultured for 72 hours or 120 hours (patient no. 2). Cells were seeded at 2 × 10^4/200 µL/well or 1 × 10^4/200 µL/well (patient no. 2). Cells were pulse labeled with methyl-^{3}H thymidine (2 Ci/mmol, Amersham) at 1 µCi/mL for the last four hours of culture, and were harvested on glass-fiber filter paper using a cell harvester (Bellco Co, Vineland, NJ). ^{3}H-TdR incorporation was counted by a Packard Mark II scintillation counter. Results were expressed as the mean ± SD based on triplicate assays.

Characterization of the ATL and cultured cells. As shown in Table 1, peripheral blood ATL cells of three patients were CD 4 (OKT-4/Leu-3a)-positive, whereas those of patient no. 3 were CD 4- and CD 8 (OKT-8/Leu-2a)-positive. All cultured cells were found to be T cells (CD 2^+), and showed the same surface phenotype as the fresh ATL cells. In addition, all the cultured cells overexpressed the IL-2 receptor/Tac antigen (CD 25^+, data not shown).

Clonality analysis of the cultured T cells. As every T cell clone expresses different T cell antigen receptor, identifiable by the T cell receptor gene rearrangement, T cell clonality can be analyzed by examining the T_β gene rearrangement. Such rearrangements are visualized by decreases in the intensities of the germ line bands (*Eco*RI, 4 kb and 10.5 kb/ *Bam*HI, 23 kb; as shown in Fig 2), and by the appearance of one or two new bands. T cells obtained from the four ATL patients were found by Southern blot hybridization to consist of monoclonal populations, each with a different T_β gene rearrangement (no. 1, 3, 5, and 7 in Fig 2A, a and b). The cultured T cells also contained monoclonal populations (no. 2, 4, 6, and 8 in Fig 2A, a and b). Moreover, the T_β gene rearrangement profiles of the fresh ATL cells were identical to those of their derived T cell lines (no. 1 and 2; no. 3 and 4; no. 5 and 6; no. 7 and 8 in Fig 2A, a and b).

HTLV-I genome in the ATL leukemic and cultured T cells. In ATL, HTLV-I provirus is usually integrated as a single copy into leukemic cells, and can be detected by Southern blot hybridization using a fragment of HTLV-I cDNA as a molecular probe. *Eco*RI digestion of all four ATL patients' peripheral blood mononuclear cell DNA revealed a single band (no. 1, 3, 5, and 7 in Fig 2B). HTLV-I provirus was also detected in the cultured T cell lines (no. 2, 4, 6, and 8), although multiple bands were detected in three cases. Moreover, when the original ATL cells and their derived T cell lines were combined, a common band was

Table 1. Surface Phenotypes of ATL Cells and Their Derived Cultured T Cells

Patient No.	PBL/Cultured T cells (T)	CD 5 (%)	CD 4 (%)	CD 8 (%)	CD 2 (%)	CD 25 (%)	OK-Ia/HLA-DR (%)
1	PBL	98.9	97.2	1.3	NT	80.4	71.5
	T	NT	99.6	0.1	99.7	99.3	98.5
2	PBL	79.2	95.6	1.5	NT	92.5	91.7
	T	NT	93.1	0.7	97.4	98.8	98.7
3	PBL	NT	70.7	60.7	87.0	88.1	NT
	T	NT	31.4	97.5	99.9	99.6	NT
4	PBL	NT	89.0	3.9	92.6	20.4	43.3
	T	NT	98.9	1.2	99.5	88.1	NT

Viable cells were treated with mouse monoclonal antibodies (Leu-series, OK-series and anti-Tac) followed by staining with FITC-conjugated anti-mouse IgG goat antibody F(ab') fragment. Stained cells were examined using Ortho Spectrum III flow cytometer. Surface phenotypes were expressed based on cluster and differentiation (CD) classification.

Abbreviation: NT, not tested.

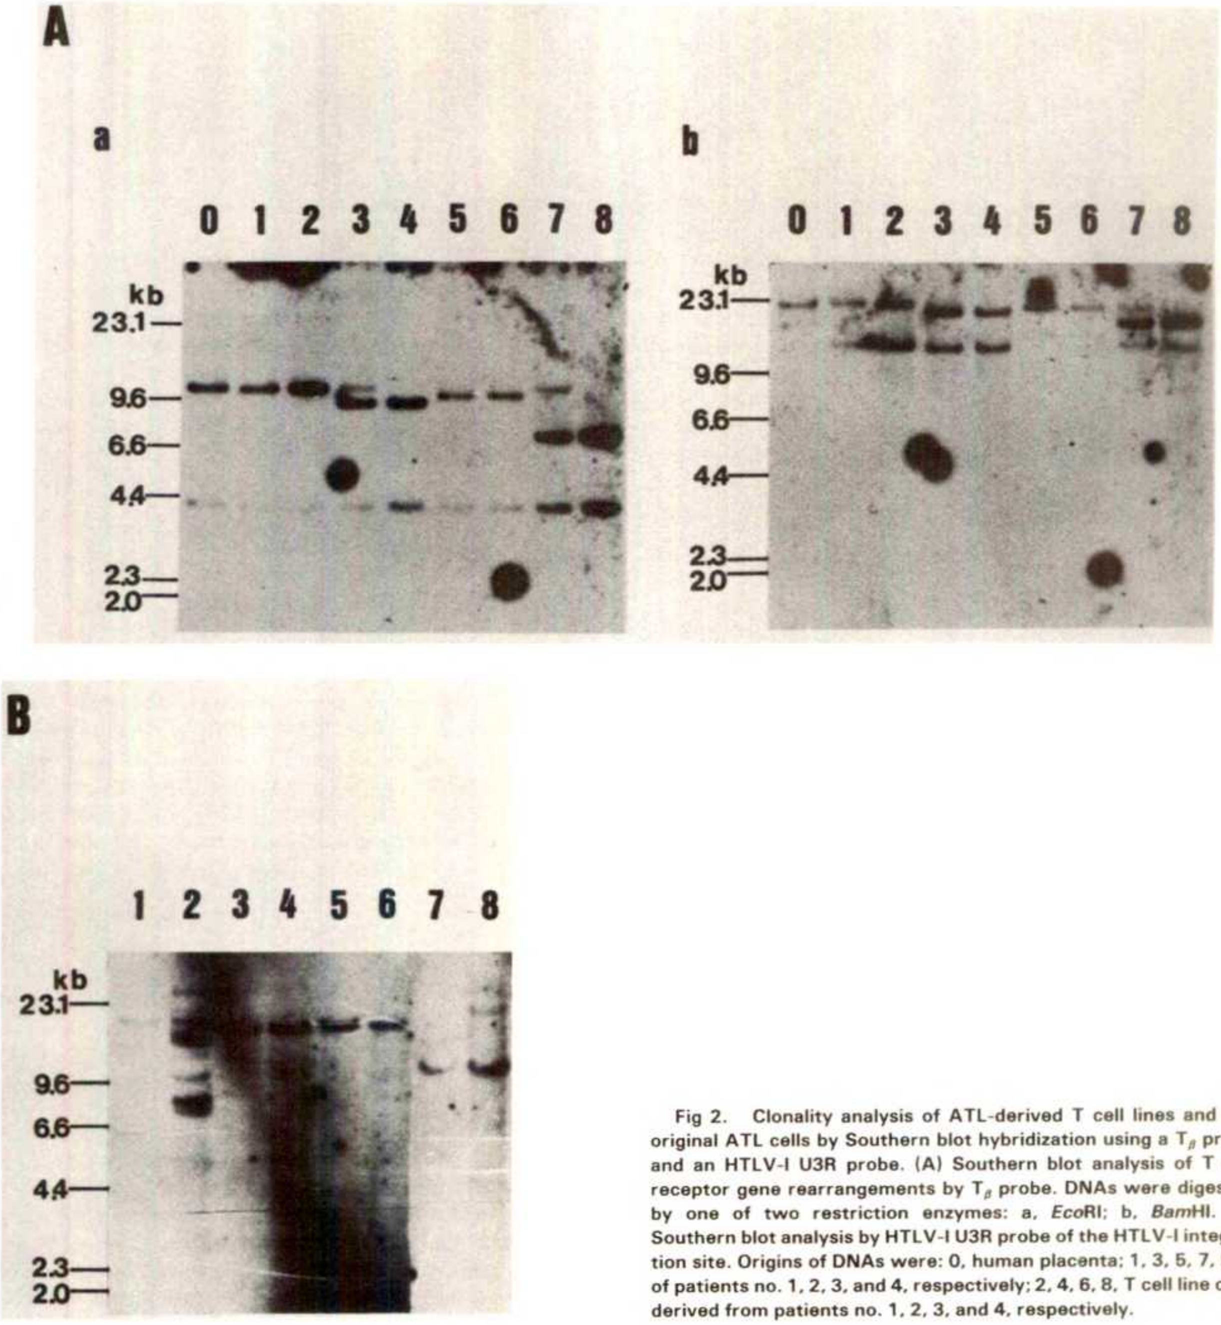

Fig 2. Clonality analysis of ATL-derived T cell lines and the original ATL cells by Southern blot hybridization using a T_β probe and an HTLV-I U3R probe. (A) Southern blot analysis of T cell receptor gene rearrangements by T_β probe. DNAs were digested by one of two restriction enzymes: a, *Eco*RI; b, *Bam*HI. (B) Southern blot analysis by HTLV-I U3R probe of the HTLV-I integration site. Origins of DNAs were: 0, human placenta; 1, 3, 5, 7, PBL of patients no. 1, 2, 3, and 4, respectively; 2, 4, 6, 8, T cell line cells derived from patients no. 1, 2, 3, and 4, respectively.

observed (no. 1 and 2; no. 3 and 4; no. 5 and 6; no. 7 and 8 in Fig 2B).

DISCUSSION

The discovery of T cell growth factor (TCGF), or IL-2, made selective long-term growth of mature T cells possible,[26] and some investigators speculated that malignant T cells with mature T cell phenotypes could be selectively grown using IL-2 as a growth factor.[17,18,20,27]

Since ATL is a leukemia of mature T cells with helper/inducer phenotype,[2,9] whose cells express IL-2 receptor constitutively,[10-12] we thought it possible that IL-2 would be an effective growth factor for them. Indeed IL-2–dependent helper T cell lines could be established from the peripheral blood of ATL patients, but clonality analyses based on the T cell receptor gene rearrangements and the site of HTLV-I provirus integration revealed that most of these T cell lines were clonally different from ATL cells. They are believed to have been derived from HTLV-I–infected nontransformed T cells.[20,28] From a patient with chronic ATL, however, we established an IL-2–dependent T cell line that had the same T cell receptor gene rearrangement and HTLV-I genome integration profiles as the original leukemia cells.[20] From this ATL patient, we sequentially established four IL-2–dependent leukemic T cell lines, including the newly established T cell line derived over 7 months from patient no. 4 described here. The findings of IL-2 responsive ATL cells in his peripheral blood suggested that ATL cells might at some time during the disease be IL-2–responsive. Therefore, we attempted to grow IL-2–dependent T cells from more than 25 ATL patients, and subjected the cells obtained to clonality analysis to determine whether they were derived directly from the original ATL cells. To date, we have identified four ATL patients from whom ATL cell clones could be grown as IL-2–dependent T cell lines.

Although it was reported that leukemic cells of most patients with ATL did not respond to IL-2,[21] despite constitutive IL-2 receptor expression, some cases of IL-2–responsive ATL including our studies have recently been reported.[29]

An important question arises as to whether these IL-2–responsive ATL cases have clinical features distinct from the majority of ATL cases in which leukemic cells do not respond to IL-2. Although our first IL-2–responsive ATL case had a chronic clinical course, only one of the other three cases had a chronic to subacute course. Further clinical studies are required to delineate this point.

Furthermore, it has been found that ATL-derived IL-2–dependent T cells become IL-2–independent during long-term culture.[17-19,30] We also isolated IL-2–independent leukemic T cell clones from the IL-2–dependent T cell lines in patient no. 4 (unpublished).

These results suggest the presence of an IL-2–dependent growth phase of leukemic cells in some ATL patients. Such a phase may be in the early stages of ATL, because leukemic cells in the majority of ATL cases do not respond to IL-2. To examine this possibility in vivo, a follow-up study over 3 years on the patient no. 4 is in progress. It is worth mentioning that freshly isolated ATL cells of patient no. 1 grew in an autocrine fashion.[29]

ACKNOWLEDGMENT

We thank Drs Kazumasa Usami, Mamoru Sato, Takashi Inamoto, Kaori Nasu, and Kenkichi Kita for providing sample materials, and Drs Shunzo Namiuchi, Yutaka Tagaya, Masafumi Okada, and Shinichi Araya of Kansai-Igaku-Kensa Center for excellent technical help. We also thank Daniel Mrozek for reading the manuscript.

Acute Nonlymphocytic Leukemia Following Etoposide and Cisplatin Combination Chemotherapy for Advanced Non–Small-Cell Carcinoma of the Lung

By Mark J. Ratain, Lynne S. Kaminer, Jacob D. Bitran, Richard A. Larson, Michelle M. Le Beau,
Consuelo Skosey, Sandy Purl, Philip C. Hoffman, James Wade, James W. Vardiman,
Karen Daly, Janet D. Rowley, and Harvey M. Golomb

Combination chemotherapy is frequently used in the therapy of advanced non-small-cell lung cancer (NSCLC), but late complications are rarely recognized because of the short survival of most patients. Of 119 patients with advanced NSCLC treated with cisplatin and other drugs, four patients developed acute nonlymphocytic leukemia (ANLL). All four patients received etoposide and cisplatin with or without vindesine. Leukemia was diagnosed at 13, 19, 28, and 35 months after start of treatment. Three patients had morphologic and/or cytogenetic features of acute leukemia with significant monoblastic involvement; the fourth patient had trilineage dysplasia and cytogenetic abnormalities more commonly associated with therapy-related leukemia. Detailed analysis of the subgroup who survived longer than 1 year (24 patients) suggests that high cumulative doses of etoposide are leukemogenic; the median etoposide dose was 6,795 mg/m^2 (first year only) in the four leukemic patients compared with 3,025 mg/m^2 in the 20 nonleukemic patients ($P < .01$). The rate of ANLL was 0.30 per person-year after the first year (95% confidence limits 0.11 to 0.90), with a cumultative risk of 15% ± 11% at 2 years, and 44% ± 24% at 2.5 years. We conclude that high doses of etoposide are potentially leukemogenic, and can induce a syndrome with features of acute monoblastic leukemia de novo that is distinct from other secondary leukemias.

©1987 by Grune & Stratton, Inc.

ACUTE NONLYMPHOCYTIC LEUKEMIA (ANLL) is a known late complication of chemotherapy and/or radiotherapy.[1-12] Most reports to date explicitly implicate alkylating agents as the leukemogenic factor,[3,4,7] and the incidence of ANLL is higher in those patients treated with both alkylating agents and radiotherapy.[1] Therapy-related ANLL (t-ANLL) may be morphologically[13] and cytogenetically[9-11] distinguishable from acute leukemia arising de novo. Initial reports of t-ANLL were primarily among long-term survivors after curative therapy for Hodgkin's disease and non-Hodgkin's lymphomas.[1,2] More recently, this late complication of cytotoxic therapy has been reported in patients with small-cell carcinoma of the lung[5,6] and other solid tumors.[3,4,8,9,11,12]

Combination chemotherapy (often containing alkylating agents) is frequently used in the management of patients with advanced non–small-cell lung cancer (NSCLC), but late complications of therapy are rarely recognized due to the short survival of most patients.[14] Many recent studies have used cisplatin-based regimens, often in combination with etoposide and/or vindesine[14-16] to exploit possible synergy.[17]

We recently suggested in a preliminary report that the combination of cisplatin, etoposide, and vindesine is highly leukemogenic, based on the development of ANLL in three of 24 lung cancer patients who survived 1 year or more.[18] After further follow-up of this cohort of 24 patients, we now report a fourth case of ANLL. Analysis of these patients provides circumstantial evidence that etoposide may be the leukemogenic agent, and that etoposide may induce a leukemia with the morphologic and cytogenetic features of acute monoblastic leukemia (AMoL), rather than those more commonly seen in t-ANLL due to alkylating agents.

MATERIALS AND METHODS

From February 1981 to September 1984, 119 patients with stage III NSCLC were treated with cisplatin-containing regimens at the University of Chicago and Michael Reese Medical Centers. Patients with metastatic disease were entered into a phase III trial comparing three cisplatin-based regimens (Table 1) with a fourth arm using cyclophosphamide, doxorubicin, methotrexate, and procarbazine (CAMP).[19] Patients with unresectable stage IIIM$_0$ disease were entered in a phase II trial of vindesine, etoposide, and cisplatin (VEP) using the same schedule described in Table 1. The patients who received CAMP have been excluded from the present analysis, since they received cyclophosphamide, a known leukemogenic drug,[7,12] although there were no patients with secondary leukemia in this cohort of 35 patients, of whom five survived at least 1 year.

Eligibility criteria included: histologically confirmed NSCLC of stage IIIM$_1$, or stage IIIM$_0$ with either malignant pleural effusion or T$_3$ lesions with mediastinal involvement; no prior chemotherapy; creatinine clearance >70 mL/min; and a Zubrod performance status ≤3. All patients were advised of procedures and attendant risk, and gave informed consent, in accordance with federal and institutional guidelines. Patients were hospitalized for administration of cisplatin to ensure adequate hydration. Cisplatin was administered over six to eight hours with mannitol diuresis. Etoposide and vindesine were administered in the outpatient clinic, using a 30 to 60

Table 1. Dose Schedules for VP, EP, VEP Regimens

Regimen	Drugs	Dose	Schedule and Route
VP	Vindesine	3 mg/m^2	Weekly IV for 12 weeks, then biweekly
	Cisplatin	120 mg/m^2	Every 3 weeks IV for 12 weeks, then every 6 weeks
EP	Etoposide	300 mg/m^2	Weekly IV for 12 weeks, then biweekly
	Cisplatin	120 mg/m^2	As per VP
VEP	Vindesine	3 mg/m^2	As per VP
	Etoposide	300 mg/m^2	As per EP
	Cisplatin	120 mg/m^2	As per VP and EP

Abbreviation: IV, intravenously.

minute infusion for etoposide and a rapid bolus for vindesine. Patients received at least two cycles (6 weeks) of therapy before re-evaluation. The therapy was discontinued in the event of progressive disease, unacceptable toxicity, or patient request. Palliative radiotherapy was allowed at any time.

Twenty-four patients survived for more than 1 year after initiation of therapy (either chemotherapy or radiotherapy), and these patients were analyzed further for risk factors for ANLL. Patients who survived <1 year were not considered to be at risk of developing ANLL because the reported latent period for this complication is rarely this short.[7,9,12,20] (In fact, none of these 95 patients were noted to develop ANLL.) The observation period was defined as time from start of therapy to death, ANLL (or the preleukemic phase), or September 18, 1986. The risk period was defined as the observation period following the first year. Risk estimates were determined by dividing the number of failures by the total person-years of risk, and an asymptotic maximum likelihood estimation was used to determine 95% confidence limits.[21] The cumulative risk of ANLL was also estimated according to the method of Kaplan and Meier.[22] The Mann-Whitney test was used to detect differences between the leukemic and nonleukemic patients.

RESULTS

Of the 24 1-year survivors, 17 were men and seven were women. The median age was 56 years (range, 38 to 69 years). Eighteen patients had metastatic disease, and six were stage IIIM$_0$. Twelve patients had adenocarcinoma, eight patients had squamous cell carcinoma, and four patients had large cell undifferentiated carcinoma. Three patients received only vindesine and cisplatin, nine patients only etoposide and cisplatin, and 12 patients received all three drugs. Nineteen patients received radiotherapy to limited fields, usually in the thorax. Only two patients received pelvic radiation. The median dose in the 19 patients was 30 Gy (range, 12 to 60 Gy).

Nineteen patients died after a median survival of 15 months (range, 12 to 26 months) without evidence of ANLL, one patient is alive (for 32 months) without evidence of ANLL, and four patients developed ANLL. The clinical and pathologic features of the latter group are summarized in Table 2, and their individual case reports follow.

Patient No. 1

A 57-year-old woman presented in September 1981 with bilateral pulmonary nodules. Bronchoscopy was positive for adenocarcinoma. In November 1981, she began therapy with cisplatin and etoposide. A partial response was documented in December 1981. Cisplatin was discontinued in April 1983 due to mild renal insufficiency, but etoposide was continued until March 1984. Blood counts at that time were hematocrit 22%, WBC count 3,700/μL, and platelets 65,000/μL. In April 1984, bone marrow aspiration and biopsy demonstrated a normocellular marrow with myelodysplasia but <5% myeloblasts. She was treated with cis-retinoic acid for 3 months without improvement. A second bone marrow examination in November 1984 was hypercellular with trilineage dysplasia and 25% to 30% myeloblasts. Cytogenetic analysis demonstrated a mosaic female karyotype characterized by three related abnormal clones, each with abnormalities of chromosomes 5 and 7 (Table 2). No further therapy was administered, and the patient died in November 1984.

Patient No. 2

A 58-year-old woman presented in May 1982 with a right lung mass and pleural effusion. Sputum cytology and thoracentesis were positive for adenocarcinoma. A bone scan showed increased uptake in the thoracic spine and right femur consistent with metastases. In June 1982, she began receiving VEP therapy with stabilization of her disease. In December 1983, she presented with dementia and ataxia. Lumbar puncture revealed malignant cells consistent with adenocarcinoma in the spinal fluid. An Ommaya shunt was implanted, and intraventricular methotrexate therapy (with oral

*First year only.

folinic acid) was administered weekly. In January 1984, her WBC count was noted to be 64,000/μL, mostly monoblasts. The bone marrow was hypercellular with ~80% monoblasts and promonocytes, consistent with AMoL. Cytochemical staining supported the monocytic origin of the leukemic cells, as the alpha naphthyl esterase reaction was strongly positive in 89% of the marrow blasts and was completely inhibited by sodium fluoride. Cytogenetic analysis demonstrated a reciprocal translocation of the short arms of chromosome 10 and the X chromosome (Table 2). Treatment was begun with low-dose subcutaneous cytosine arabinoside (10 mg/m^2 twice daily), but the patient died ten days later of acute renal failure.

Patient No. 3

A 59-year-old man presented in February 1984 with a left pleural effusion. Thoracentesis and pleural biopsy were both positive for adenocarcinoma. Radiotherapy to the left hemithorax (30 Gy in 15 fractions) was administered in March 1984. He began receiving VEP therapy in April 1984, which was complicated by acute renal failure. In May 1984, therapy was restarted using only etoposide and vindesine. He continued without evidence of disease progression until January 1985 when a complete spinal cord compression (at T-8) was diagnosed. A laminectectomy was performed, followed by an additional 20 Gy (10 fractions) to the thoracic spine. In April 1985, the patient complained of severe fatigue, and a complete blood count revealed a hematocrit of 21%, WBC count of 1,100/μL, and a platelet count of 218,000/μL. A bone marrow biopsy demonstrated total replacement of the marrow by malignant cells, initially felt to be metastatic adenocarcinoma, but later confirmed as poorly-differentiated AMoL. Cytogenetic analysis demonstrated a reciprocal translocation involving the short arm of chromosome 9 and the long arm of chromosome 11 (Table 2). The patient was treated with cyclophosphamide 1,000 mg/m^2 and doxorubicin 40 mg/m^2 monthly for four cycles, and had no residual leukemia in September 1985. A follow-up bone marrow exam 2 months later also showed no evidence of leukemia, but the patient died of progressive carcinoma in January 1986.

Patient No. 4

A 70-year-old woman presented in August 1983 with a right lung mass. Needle aspiration of the mass was positive for adenocarcinoma. Chest computed tomography (CT) scan demonstrated bilateral hilar and mediastinal adenopathy, a right middle lobe mass, and an enlarged left adrenal gland. In October 1983 she was begun on etoposide and cisplatin but received only one dose of cisplatin secondary to deteriorating renal function. She continued to receive etoposide until August 1985, at which time disease progression was noted. In September 1986, her blood counts were hemoglobin 7.5 gm/dL, WBC count 1,900/μL and platelets 58,000/μL. The bone marrow was hypercellular with 50% blasts. Cytochemical staining of the marrow showed that 41% of the blasts were positive for alpha naphthyl esterase and 27% were positive for alpha naphthyl butyrate esterase, consistent with acute myelomonocytic leukemia. Cytogenetic analysis demonstrated a complex reciprocal translocation involving the short arm of chromosome 9, the long arm of chromosome 11, and the long arm of chromosome 18 (Table 2). The patient refused further therapy and died 1 month later.

Risk of ANLL

The 24 patients in this study population were at risk for a total of 13.4 person-years (after the first year) before death, ANLL, or this report. This yields a rate of ANLL of 0.30 per person-year, with 95% confidence limits of 0.11 to 0.80. In comparison, the rate of death from bronchogenic carcinoma during the same period was 1.42 per person-year (95% confidence limits are 0.91 to 2.23). The cumulative risk of ANLL by Kaplan-Meier analysis was 15% ± 11% at 2 years and 44% ± 24% at 2.5 years (Fig 1).

Comparison of Leukemic and Nonleukemic Patients

Nonparametric testing (Mann-Whitney) was used to compare the leukemic (n = 4) and nonleukemic patients (n = 20). There were no significant differences in the cumulative vindesine or cisplatin doses during the first year of observation (Table 3). However, the patients who eventually developed ANLL had received significantly more etoposide than the nonleukemic patients (Table 3, Fig 2).

DISCUSSION

This is the first report of ANLL following combination chemotherapy with cisplatin and etoposide. None of the leukemic patients ever received classical alkylating agents that have previously been associated with the development of t-ANLL.[3,4,7,12] Also, radiotherapy does not appear to be causative in these cases, since only patient no. 3 received radiotherapy and only to a limited thoracic port, not to the pelvis as has previously been associated with t-ANLL.[9]

Our circumstantial data suggest that high cumulative doses of etoposide may be causative in the development of ANLL. All four leukemic patients received both cisplatin and etoposide, but patients no. 3 and 4 received only a single dose of cisplatin because of nephrotoxicity. In fact, this allowed these patients to receive higher doses of etoposide. As shown in Fig 2, there appears to be a relationship between the total dose of etoposide during the first year of therapy and the development of ANLL. Other reports have suggested a similar dose effect for the alkylating agents.[3,12,23] However, we cannot exclude the possibility that the other known leukemogenic factors present in these patients (ie, smoking, radiation therapy, cisplatin), or even unknown factors such as the Tween 80 required for formulation of the etoposide, were contributory to the development of ANLL, especially in patients no. 2, 3, and 4.

The risk of ANLL in our patient population probably exceeds 11% per person per year with a cumulative risk of 44% ± 24% at 2.5 years, which is much higher than that

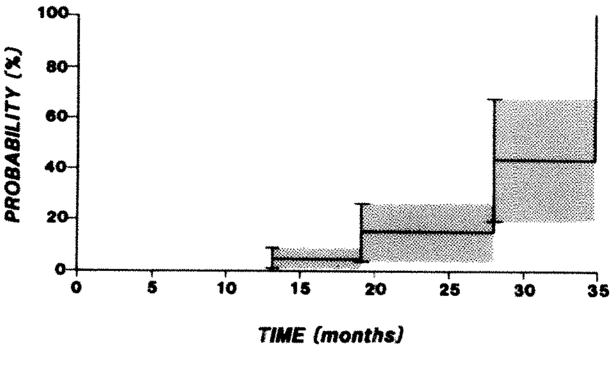

Fig 1. Cumulative risk of secondary ANLL in 119 patients (24 1-year survivors) treated for NSCLC with cisplatin-containing regimens (Kaplan-Meier estimate). Vertical markings represent ± SE.

calculated in previous reports of t-ANLL. For example, Pederson-Bjergaard et al[7] estimated a risk of 1% to 1.5% per year after reviewing ~2,000 patients treated with alkylating agents for a variety of tumors. Greene et al recently assessed leukemogenic risk factors in women treated for ovarian carcinoma.[12] The overall 10-year risk was 8.5% ± 1.6%, with a cumulative risk of 19.5% ± 4.9% at 10 years in women who received >27,000 mg of melphalan, the subset at highest risk.

Although cisplatin and etoposide are often used in the management of germ cell tumors and small cell carcinoma of the lung,[24,25] there have been no reports of this combination being leukemogenic. This may be due either to differences in scheduling, or to the relatively low cumulative doses of etoposide received by these patients. In four 3-week cycles of cisplatin/etoposide as usually administered to patients with germ cell tumors, only 2,000 mg/m² etoposide is administered, using 100 mg/m² daily doses. Similar schedules have been used in small cell carcinoma,[25] with etoposide doses of 300 to 500 mg/m² per 3- to 4-week cycle. Thus, it is quite possible that the high incidence of ANLL in our patients is due to the unusual schedule and dose intensity of etoposide used in this study (Table 1). Our four leukemic patients received ~4,000 to 8,000 mg/m² of etoposide in 1 year, and the nonleukemic patients received a median of ~3,000 mg/m² for their NSCLC, usually 300 mg/m² per week.

Etoposide-induced ANLL may represent a new syndrome that differs from classical t-ANLL.[9,13] Although the clinical features of three of these patients raise the question whether they actually represent ANLL de novo, this is statistically unlikely. Patient no. 1 had trilineage dysplasia and the cytogenetic abnormalities of chromosomes 5 and 7 frequently observed in t-ANLL, but the other three patients had the morphologic and/or cytogenetic characteristics usually seen with AMoL. Moreover, patients no. 2, 3, and 4 lacked a preleukemic phase, which was noted in 76% of the 63 patients with t-ANLL reported by Le Beau et al.[9] Finally, the latency period from the start of therapy to overt leukemia in patients no. 2 and 3 was short, ie, 13 and 19 months. This compares with a median of 58 months in the study of Michels et al[8] and to a median of 56 months in the 63 patients with t-ANLL in our previous series.[9] However, Pedersen-Bjergaard et al recently reported four patients (of six) with small cell carcinoma of the lung who developed ANLL after a latency period of <2 years.[6]

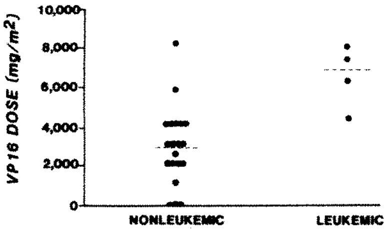

Fig 2. **Comparison of cumulative etoposide doses received by the leukemic and nonleukemic patients. The median cumulative etoposide dose (indicated by the bar) was significantly higher in the leukemic patients ($P < .01$, Mann-Whitney). The sole nonleukemic patient alive without ANLL received 2,005 mg/m² of etoposide. (VP-16, etoposide).**

As noted earlier, most patients with t-ANLL secondary to alkylating agents have losses of all or part of the long arm of chromosomes 5 and 7, and these abnormalities were present in patient no. 1. Two of our patients, however, had chromosome abnormalities characteristic of AMoL, namely translocations involving chromosomes 9 and 11, with breakpoints at 9p22 and 11q23.[26] AMoL has rarely been observed as a therapy-related leukemia; it did not occur in any of the 26 cases reported on by Rowley et al.[11] It is of interest that we have also studied one other patient who developed secondary AMoL, but she had been treated for ovarian carcinoma with alkylating agents. Michels et al noted two cases of AMoL in their series of 65 patients with secondary leukemia.[8] Two other patients with a secondary AMoL and a t(9;11) have been reported on separately by Weh et al[27] and Dewald et al.[28] The child described in the former report received combination chemotherapy including teniposide, another epipodophyllotoxin and a topoisomerase II inhibitor,[29] and cisplatin, and AMoL was diagnosed 38 months after beginning therapy; there was no preleukemic phase. The patient reported on by Dewald et al[28] also did not have a preleukemic phase before presentation with AMoL 7 years after therapy.

Weh et al proposed that acute leukemias with a specific translocation be considered primary, not secondary, leukemias.[27] This recommendation is based on their concern that such patients might otherwise not be treated in view of the generally poor response of patients with t-ANLL to therapy. Three of our own patients plus the other five cases noted had features usually associated with AMoL de novo, and these leukemias may have developed independent of the prior cytotoxic therapy received. A similar argument may be made for three other patients whom we have studied, each of whom developed acute promyelocytic leukemia with a t(15;17); two had received radiotherapy only, neither had a preleukemic phase, and the latent period was 23 and 56 months.[9] However, it is equally plausible that these specific chromosomal rearrangements were induced by mutagenic treatment, and that once these genetic rearrangements had occurred, the subsequent leukemia manifest the same clinical features typically seen when that particular chromosomal abnormality occurs spontaneously. For reasons not yet clear, it seems likely that high doses of etoposide, and possibly teniposide,[27] may induce genetic mutations that result in acute leukemia with a monoblastic phenotype.

The mechanism for malignant transformation by etoposide may differ from that of alkylating agents due to the different molecular pharmacology of these drugs. Alkylating agents are cytotoxic because of their ability to form cross-links with DNA.[30] Etoposide also interacts with DNA, by forming a ternary complex with topoisomerase II, which blocks the catenation activity of the enzyme leading to DNA strand breakage.[29,31] It has also been suggested that etoposide may cause DNA damage via a dehydrogenase-induced free radical intermediate.[32] In addition, it is possible that cisplatin may have contributed to the leukemogenesis in these patients, since it also acts to cross-link DNA.[33]

Although etoposide has not previously been demonstrated to be leukemogenic in humans, the topoisomerase II inhibitors are extremely potent clastogens in vitro, producing a high frequency of sister chromatid exchange and other chromosomal aberrations.[34-37] The mutagenicity of the closely related drug teniposide appears to be highly site-specific,[37,38] and thus teniposide-induced (or etoposide-induced) neoplasms might produce a unique clinical syndrome. Oncologists must be alert to the fact that increasing numbers of patients are being exposed to very potent mutagenic chemicals in an effort to treat malignant diseases effectively. The careful description of untoward consequences of some of these drugs, especially when used at high doses, will help to minimize these consequences. Thorough investigation of the few patients who unfortunately develop leukemia will provide critical insights into the mechanisms associated with leukemogenesis.

ACKNOWLEDGMENT

The authors thank Dr Richard Schilsky for his many helpful comments and Dora Currin for preparation of the manuscript.

NOTE ADDED IN PROOF

Fenaux et al[39] recently reported a case of AMoL following combination chemotherapy for osteosarcoma, associated with t(9;11)(p21;q23). This case also had a short latency period of 11 months, but the patient did not receive either etoposide or cisplatin.

B Lymphocyte Precursors and Myeloid Progenitors Survive in Diffusion Chamber Cultures but B Cell Differentiation Requires Close Association With Stromal Cells

By Philip C. Kierney and Kenneth Dorshkind

The aim of this study was to investigate the relative contribution of direct contact with stromal cells *v* stromal cell-derived soluble mediators to the differentiation of B lymphocytes and cells from other hematopoietic lineages. This was investigated by making a comparison between hemopoietic cells grown in direct contact with stroma to those in diffusion chambers (DCs) placed over purified populations of stroma. The source of stromal cells was adherent layers from myeloid or lymphoid long-term bone marrow cultures that had been treated with mycophenolic acid, an antibiotic that depletes hemopoietic cells from the cultures but retains a functional stroma. The cells seeded into the chambers were fresh marrow cells that had been passed through two consecutive nylon wool columns to deplete cell populations capable of forming an adherent cell layer in vitro. DCs were placed in wells in which the adherent stroma, growing under myeloid or lymphoid conditions, was present. The results indicate that progenitors of granulocytes and macrophages survived and differentiated in DCs under myeloid culture conditions, as the number of cells and absolute number of CFU-GM increased over that present in the reseed population. These levels, however, were markedly less than in parallel cultures in which the cells were seeded directly onto stroma. Hematopoiesis in DCs placed over hemopoietically active stroma was not optimal, suggesting that factors were used by those hemopoietic cells closest to the stroma. A B lymphocyte precursor survived in DCs under myeloid but not lymphoid conditions, and its differentiation into B lymphocytes was dependent on close association with stromal cells; B lymphopoiesis initiated when cells from DCs grown under myeloid conditions were harvested from the chambers and seeded directly onto stroma initiated and maintained under lymphoid bone marrow culture conditions. B lymphopoiesis did not initiate if the DC from the myeloid conditions was left intact and placed directly over a lymphoid stromal cell layer in lymphoid conditions.

© 1987 by Grune & Stratton, Inc.

THE PRIMARY production of B lymphocytes occurs in the bone marrow in postnatal life.[1-3] B lymphopoiesis, as well as the development of myeloid and erythroid cells, proceeds in the medullary cavity in association with a supporting population of stromal cells that creates a hematopoietic microenvironment that is apparently obligate for blood cell formation.[4-6] Although stromal cells are generally accepted to play a regulatory role in hematopoiesis, how they mediate their regulatory effects on developing B lineage cells remains incompletely understood.

Substantial evidence from both in vivo and in vitro morphological studies shows that direct stromal cell–hemopoietic cell contact is important, and associations between B cells and stromal cell processes have been observed using immunoelectronmicroscopic techniques.[7] Intracellular contacts resembling gap junctions have been suggested to be of possible importance in transmitting signals from the stroma to blood cells[8,9] although this has not been formally demonstrated in the development of B lymphocytes. Results from different long-term bone marrow culture systems, in which long-term hematopoiesis is dependent on the formation of a stromal cell adherent layer,[10] also suggest a role for direct contact in B lymphopoiesis. The myeloid bone marrow culture system (MBMC) of Dexter and colleagues is optimal for the growth of myeloid precursors and their differentiation into mature end cells.[11] B lymphocytes and their immediate precursors are not present in the cultures, but an early B cell precursor is present.[12,13] A higher proportion of these precursors,[12] as well as other progenitor populations,[14] is present in association with the adherent layer as compared with the nonadherent populations in the cultures.[12,14] Blood cells in the adherent layer of the MBMC are often covered by epithelial-like cells,[15] and such close interactions may also be observed in the lymphoid bone marrow culture system (LBMC) described by Whitlock and Witte.[16] B lymphopoiesis proceeds in those cultures but not myelopoiesis.[16] The lymphoid cells in the LBMC can often be observed to be enveloped by cytoplasmic infoldings of a single stromal cell.[17] Hemopoiesis is clearly also regulated by various hemopoietic growth factors,[18] some of which are produced by stromal cells.[19-22] Several laboratories have now isolated stromal cell lines that support proliferation and/or differentiation of B lineage cells. Some of these lines mediate their functions in part through secretion of soluble mediators[23-25].

Possibly only selected stages of B lymphopoiesis proceed under the influence of stromal cell-derived growth factors alone, and close stromal cell interactions may be required at certain points in that differentiative process. Distinguishing between these alternatives could be important in defining the signals that regulate B cell production from primitive hematopoietic precursors. This issue was investigated by comparing the growth of B lineage cells grown in direct contact with stromal cells to those seeded in diffusion chamber (DC) cultures placed over purified populations of stromal cells.

The results indicate that B cell precursors, as well as myeloid progenitors and their differentiated progeny, can survive in DCs but that hematopoiesis is not as optimal as when direct stromal cell contact is permitted. The data further indicate that the differentiation of the MBMC B cell precursor into B lymphocytes only occurs when direct stromal cell contact is permitted.

MATERIALS AND METHODS

Animals. Six- to 8-week-old male or female BALB/cAn mice were produced in the vivarium of the Division of Biomedical Sciences, University of California, Riverside, from the breeding stock obtained from Life Sciences Laboratories, St. Petersburg, FL.

Preparation of cell suspensions. Mice were killed by cervical dislocation, and femurs were removed and placed in α-minimal essential medium (α-MEM; GIBCO, Grand Island, NY). Single cell suspensions of bone marrow were obtained by flushing the plug from bones with 3 mL medium. Cell viability was determined by eosin dye exclusion, and all cell counts were performed in a hemocytometer.

Generation of stromal cell cultures and stromal cell lines. Stromal cell cultures were generated by establishing long-term bone marrow cultures under myeloid or lymphoid conditions and subsequently treating these with the antibiotic mycophenolic acid, MPA, GIBCO). As previously described in detail, this procedure results in the depletion of hemopoietic cells while retaining a viable, functional adherent layer of stromal cells.[22] Purified stromal cells initiated under myeloid conditions were established by plating 4 mL of a bone marrow cell suspension at 10^6 cells/mL in α-MEM supplemented with 20% horse serum (GIBCO) and 10^{-6} mol/L hydrocortisone succinate (Upjohn, Kalamazoo, MI) in each 9.5-cm^2 well of a six-well plate (Costar, Cambridge, MA). Cultures were placed in a 33°C incubator and wrapped in Saran Wrap to prevent drying of cultures. Cultures were fed after 1 week, and by 2 weeks a confluent, adherent layer of cells had been established. At that time, all culture medium was removed from the wells and replaced with the above medium additionally supplemented with 5 μg/mL MPA. Three days later, all the MPA-containing medium was replaced by fresh medium and, following a 3-day incubation, the cycle was repeated. Purified stromal cells initiated under lymphoid conditions were similarly established as above except that the medium consisted of RPMI 1640 supplemented with 5% fetal calf serum (FCS) (GIBCO), and 5×10^{-5} mol/L 2-mercaptoethanol (2-ME), and all incubations were carried out in a 5% CO_2 and air incubator at 37°C. Cultures were fed once a week in their respective medium.

The preparation of stromal cell lines and their characteristics has been described in detail.[23] One of these, S17, was isolated from a myeloid bone marrow culture adherent layer and has the capacity to support B cell precursors and their differentiation into surface IgM expressing B lymphocytes. This line was grown to confluency in 10-cm^2 dishes and α-MEM plus 15% FCS. Cells from these dishes were harvested by trypsinization and subcultured in each 9.5-cm^2 well of a six-well plate (Costar).

Separation of cells on nylon wool columns. Cells from fresh bone marrow were passed through nylon wool columns prepared according to the method of Julius et al.[26] As previously demonstrated, this procedure depletes stromal cells capable of forming an adherent layer in vitro but retains hemopoietic precursors.[22] A maximum of 5×10^7 fresh bone marrow cells in a 2-mL vol was loaded onto a column packed in a 12-cc syringe and washed into the nylon wool with 1 mL 37°C medium. The nonadherent cells were eluted from the column by washing with 20 mL of the above medium. The eluted cells were then passed through a second column as described above. Cells were incubated 45 minutes on each column. Approximately 7% of the initial cell input remained following passage through the second nylon wool column. To confirm the efficacy of the separation procedure, aliquots of 5×10^5 of cells passed twice through nylon wool were cultured alone in tissue culture wells and observed throughout the course of the experiment for growth of stromal or hematopoietic populations.

DC cultures. DCs were seeded with bone marrow cells that had been passed through nylon wool and placed in the wells of the cluster dishes. The chambers, suspended in each well, consisted of a low protein binding, non-tissue culture-treated nucleopore membrane with 0.4 μ pore size (Costar). The distance between the bottom of the DC membrane and the bottom of the tissue culture well is 1 mm, thus minimizing the chance that stromal cell processes could have made contact with cells in the DC through pores in the DC membrane. Cells (10^5 and passed twice through nylon wool) were seeded into the chambers, which were then placed in the tissue culture wells with preestablished stromal layers. The cultures contained a total volume of 4.1 mL, with 1.5 mL contained within the DC and an additional 2.6 mL in the well below. Cultures were fed by first removing 0.75 mL from the chamber. This chamber was then removed from the well with sterile forceps, and one-half the volume was removed from the underlying well and replaced with fresh medium. The DC was then placed back in the well, and 0.75 mL of additional fresh medium was added to it.

Cultures under MBMC conditions were maintained at 33°C in α-MEM supplemented with 20% horse serum (GIBCO) and 10^{-7} mol/L hydrocortisone succinate (Upjohn). The cluster dishes were wrapped in Saran Wrap to prevent dessication because the 33°C 5% CO_2 and air incubator was not humidified. Cultures under lymphoid conditions were maintained at 37°C in a humidified 5% CO_2 and air incubator in RPMI 1640 supplemented with 5% FCS (GIBCO) and 5×10^{-5} mol/L 2-ME.

Transfer of cultures from myeloid to lymphoid conditions. In some experiments, cultures were transferred from myeloid to lymphoid growth conditions. For those cells grown in DCs under myeloid conditions, cells were harvested, washed once, and placed in a new diffusion chamber in 1.5 mL RPMI 1640, 5% FCS, and 5×10^{-5} mol/L 2-ME. This was then transferred to the 9.5-cm^2 well in which stroma grown under lymphoid conditions was present, containing 2.6 mL of the above medium at 37°C. Alternatively, aliquots of cells from the DCs were seeded directly onto stroma in LBMC conditions. Those myeloid cultures in which nylon-wool-passed cells had been seeded directly onto stroma were transferred by pooling the nonadherent cells with the loosely adherent ones obtained by vigorously washing the wells by repeated pipetting. After one wash, these cells were then reseeded onto adherent stromal cell layers established under lymphoid conditions.

Antibody labeling of cells and fluorescence microscopy. Surface IgM-bearing cells were identified with an affinity-purified, fluorescein-conjugated, goat anti-mouse IgM antibody (Southern Biotechnology, Birmingham, AL). This reagent was diluted 1:5 in α-MEM supplemented with 5% FCS and 1 mg/mL sodium azide. Aliquots of 1 to 2×10^6 cells harvested from cultures or fresh bone marrow were suspended in 100 μL diluted antiserum and incubated for 45 minutes on ice. Cells were then washed twice at 4°C in α-MEM without serum and resuspended in 0.2 mL α-MEM. To this was added an equivalent volume of 2% paraformaldehyde in phosphate-buffered saline (PBS). Cells were stored at 4°C until cell counts were performed on wet-mount preparations using a Leitz Laborlux microscope equipped for epifluorescence. At least 500 cells were counted per sample. Those cells that expressed the 14.8 surface antigen were identified by incubating 1 to 2×10^6 cells with 100 μL rat anti-mouse hybridoma supernatant (American-type culture collection, Rockville, MD) for 30 minutes at 4°C. Following two washes, cells were resuspended in 50 μL 1:5 dilution of an affinity-purified goat anti-rat Ig (Southern Biotechnology). No cells in fresh marrow or cultures stained with this reagent alone. After a 30-minute incubation at 4°C, cells were washed twice as above and resuspended in paraformaldehyde. Fresh bone marrow controls were included in all experiments and, on the average, 9% of cells in fresh marrow were surface IgM positive and 20% expressed the 14.8 antigen.

Myeloid colony assay. Myeloid progenitor cells capable of forming colonies in semisolid medium were assayed by culturing 5×10^4 cells in 35-mm plastic Petri dishes containing 1 mL methylcellulose medium.[27] The latter contained 0.8% methylcellulose, 30% FCS, 5×10^{-5} M 2-ME (Sigma, St Louis), and 10% medium conditioned by WEHI-3B (D^-) cells. This was prepared by culturing WEHI cells at 10^6 cells/mL in 40 mL α-MEM supplemented with 1% FCS. Following a 24-hour incubation, supernatants were collected, centrifuged, and stored at 4°C until used. Colonies were enumerated on day 8.

RESULTS

Hemopoietic cell survival in diffusion chamber under MBMC conditions. To determine how the growth of cells in diffusion chambers under MBMC conditions compared with that usually observed in primary MBMC, 10^5 bone marrow cells passed twice through nylon wool were seeded in DCs placed over purified stromal cell layers. The nylon wool passage depleted stromal cells that could potentially form a microenvironment within the DC, thus ensuring that survival of hemopoietic populations would be dependent on stromal cells in the underlying well. The source of this stroma was a primary MBMC that has been treated with MPA to deplete hematopoietic cells. This growth was compared with that in DCs placed over hemopoietically active stroma or following direct seeding of the nylon-wool-passed cells on purified stromal cell layers. The data in Table 1 show the results of three such experiments in which triplicate wells were evaluated for each condition.

Hematopoietic cells were consistently recovered following seeding in DCs placed over stromal cell layers obtained by MPA treatment. Three weeks following initiation of the cultures, the number of hematopoietic cells recovered from the chambers had increased three- to sevenfold over the number initially seeded. Morphological examination of these populations showed them to be primarily neutrophilic granulocytes and macrophages, a finding consistent with the fact that 70% to 90% of the cells expressed the MAC-1 surface antigen (data not shown). The data also indicate that progenitors of granulocytes and macrophages survived under DC conditions for the 3-week observation period as the absolute number of CFU-GM had increased up to fivefold over the number in the initial seed population. In no case was the absolute number of CFU-GM present 3 weeks postinitiation less than that present in the reseed population.

A second aliquot of the same nylon-wool-passed bone marrow cells was seeded directly onto MPA-derived stromal cell layers. As shown in the middle column of Table 1, a higher level of hematopoiesis was observed in these cultures, as the numbers of cells recovered had increased up to 33 times the initial number seeded. This was generally reflected in the number of CFU-GM present; in experiment 2, the numbers of these progenitors had increased to 91 times the numbers in the reseed population.

A third aliquot of the above cells was seeded into DCs placed over hematopoietically active stroma. These cultures were established by simultaneously seeding 10^5 of the nylon-wool-passed bone marrow cells into DCs and directly onto the MPA stromal cell layers over which the chambers were placed. The use of reseeded, MPA-treated stroma in this third condition ensured that the stromal cells in all experiments were manipulated in a comparable manner. The number of hematopoietic cells recovered from these DCs 3 weeks postseeding had decreased twofold in one experiment and had doubled in the other two. These conditions were not optimal, however, since the numbers of CFU-GM present were always less than in the initial nylon-wool-passed reseed population.

In all experiments, aliquots of nylon-wool-passed cells were seeded directly into empty wells. No adherent layer formed under these conditions, and hematopoietic cells did not survive past 1 week. Neither did hematopoiesis initiate in DCs placed into wells in which no adherent stromal layer was present. Before they were used, MPA-treated stromal cell cultures were observed for 2 weeks following the last drug treatment to ensure that hematopoiesis did not initiate from drug-resistant precursors.

Survival of B cell precursors in DCs. An early B cell

Nylon-wool-passed bone marrow (10^5) seeded into DCs placed over MPA-purified stroma, directly onto MPA stroma, or in DC over stroma on which 10^5 hematopoietic cells had been seeded in parallel. Number of CFU-GM/10^5 in reseed population in experiments 1, 2, and 3 were 125, 83 and 280, respectively. Each experiment represents triplicate cultures per condition. Numbers indicate mean ± SD.

precursor, but not pre-B or mature B cells, is present under MBMC conditions in which direct contact with the stroma is permitted,[12,13] and these cells can be induced to differentiate into mature B cells following transfer to LBMC conditions.[28,29] This is demonstrated by the data in Table 2 in which nylon-wool-passed cells were seeded onto stromal cell layers under MBMC conditions (condition 1, Table 2); 3 weeks later, the cells were harvested and replated on LBMC stroma under LBMC conditions. As shown in Table 2, cells that expressed surface IgM were induced by 4 weeks later.

To determine whether the MBMC B cell precursor also survived in DCs under MBMC conditions for 3 weeks, cells from cultures were either transferred to a new DC that was placed over a stromal cell adherent layer established by treating a primary LBMC with MPA (condition 2, Table 2) or harvested from the DCs in MBMC conditions and plated directly onto LBMC stroma (condition 3, Table 2). These cultures were then maintained at 37°C in LBMC medium. Less than 5×10^5 cells were recovered from DCs after 4 weeks in LBMC conditions, and no IgM-expressing cells were included among this population. This was consistent with morphological observations that demonstrated these cells to be granulocytes and macrophages. It is not clear why these myeloid cells survived under the LBMC conditions, but very low levels of colony-stimulating factors sufficient to allow this could have been secreted by the stromal cells under lymphoid conditions. A markedly different profile was observed in cultures in which cells had been seeded directly on stroma (condition 3). Up to 2×10^6 cells were recovered from these cultures, and up to 10% expressed surface IgM. Morphological examination demonstrated virtually all these cells to be lymphoid. These data indicate that a B cell precursor can survive in DCs under MBMC conditions but requires a close association with stromal cells to differentiate into surface IgM-positive B cells.

The adherent layers in LBMC conditions onto which DC cells were seeded were MPA-treated LBMC stroma. This left open the possibility that the sIgM-positive B cells detected could have arisen from MPA-resistant precursors present in the adherent layer. To ensure that the B cells were indeed derived from the DC cells, replicate experiments were performed in which 10^5 nylon-wool-passed cells were seeded into DCs over MPA-treated stroma under MBMC conditions. Following a 3-week incubation period, cells were harvested from the chambers and plated onto a confluent layer of S17, a stromal cell line shown to support B cell differentiation,[23] under LBMC conditions. Three separate experiments were performed, and the mean number of cells (± SD) recovered following 4 weeks in LBMC conditions was $2.1 \pm 0.6 \times 10^6$. Phenotypic analysis demonstrated that 48% ± 3.6% of these expressed the 14.8 antigen and 12.4 ± 7.3% were surface IgM positive. These data confirm that a B cell precursor is present in DCs and can differentiate into B cells when provided with the proper conditions.

Adherent populations of functional stroma do not establish in DCs. The conclusion that a B cell precursor survives under DC conditions is dependent on confirming that the nylon-wool-passed cells are not in contact with an adherent layer of functional stromal cells. That the nylon-wool-passed cells cultured alone do not form adherent layers and that the DC membranes are designed to prevent cell adherence suggest that this is the case. Nevertheless we considered it critical to examine the DC membrane to exclude the possibility that a functional adherent layer had established under the influence of soluble mediators produced by the stromal cells in the lower chamber.

Following 3 weeks of growth under MBMC conditions, nonadherent cells were removed from the DC growing over MPA-treated stroma in MBMC conditions. The membranes were gently washed and stained with Wright's stain. Examination of the membranes at 100x under a dissecting microscope indicated that a few foci of cells adherent to the membrane were observed in one-half of the experiments. These appeared to be macrophages, as they presented with a central nucleus and abundant cytoplasm. In view of this result, however, experiments were designed to establish whether populations of cells that could support hematopoiesis did indeed establish on these DC membranes. This was tested by placing the DC, seeded with 10^5 nylon-wool-passed cells, over a well in which MPA-derived stroma was growing under MBMC conditions. After 3 weeks, the nonadherent cells were removed from the chambers and the membranes were gently washed. The DCs were then placed over a well containing medium only in MBMC conditions and reseeded with 10^5 nylon-wool-passed cells. If a functional stromal layer had established in the DC, hematopoiesis would have been expected to initiate. Cultures were fed weekly and then examined for cell growth at 3 weeks postseeding, but no cells were recovered at that time. This experiment indicates that functional adherent layers do not establish in DCs under the experimental conditions used and suggests that the B cell precursor and CFU-GM that survive in DCs do so under the influence of soluble mediators secreted by stromal cells in the underlying well.

Table 2. Survival of B Cell Precursors in DC

Condition	Growth Under MBMC Conditions (3 weeks)	Following → Switch to	LBMC Conditions (4 weeks)	Cell No. After 4 Weeks in LBMC Conditions	IgM Positive (%)
1	Stroma	→	Stroma	$1 \times 10^6 \pm 0.1$	6.4 ± 5
2	DC	→	DC	$0.3 \times 10^6 \pm 0.15$	0
3	DC	→	Stroma	$1.4 \times 10^6 \pm 0.7$	11 ± 0.7

After 3 weeks under MBMC conditions (α-MEM, 20% horse serum, 10^{-6} mol/L steroids, 33°C), either on stroma directly or in DCs over MPA stroma layers, cultures switch to LBMC conditions (RPMI 1640, 5% FCS, 5×10^{-5} mol/L 2-ME, 37°C). Cells were left in contact with stroma, kept in DC, or removed from DC and placed directly on LBMC stroma. All data are based on two separate experiments in which three wells per condition were evaluated.

LBMC stromal cells do not support B cell precursors under DC conditions. The above experiments suggest that MBMC stromal cells produce soluble mediators that allow survival of B cell precursors in DC. Whether LBMC stromal cells can also support this precursor was tested by seeding 10^5 marrow cells passed twice through nylon wool into DCs placed over LBMC stromal cells in lymphoid conditions or directly onto the stroma. The data in Table 3 indicate that a close association with stromal cells is required for cell survival under LBMC conditions. Following 4 weeks of culture, B lymphopoiesis had not initiated and no hematopoietic cells were recovered from the DCs. Cells that expressed the 14.8 antigen and surface IgM were consistently recovered from parallel cultures in which the nylon-wool-passed cells had been directly seeded onto the stromal cell layer. These data establish that the initiation of B lymphopoiesis in LBMC requires a close association with the stroma and suggest that under LBMC conditions LBMC stromal cells do not secrete a soluble mediator that can support the B cell precursor under DC conditions.

DISCUSSION

The experiments reported herein used an in vitro DC culture system to evaluate the relative contribution of direct contact with stromal cells *v* the soluble mediators produced by them in the differentiation of B lymphocytes and other myeloid populations. The findings clearly indicate that, at least for the 3-week period of observation, hematopoiesis can proceed in DCs under MBMC conditions. Progenitors of granulocytes and macrophages were detected, and their numbers had increased over those present in the reseed population. This could indicate that self-renewal of these progenitors had occurred or that they were derived from an earlier cell through differentiation and amplification. The presence of morphologically identifiable granulocytes and macrophages in the chambers also suggests that differentiation of CFU-GM had occurred as well. A B lymphocyte precursor was detected in the DCs, but no conclusion can be drawn as to whether it is part of a stem cell pool or a restricted progenitor cell population. We must assume that the survival of these cell types was dependent on the production of soluble mediators from the underlying stroma; no cells survived in DCs placed in wells in which no stroma was present, and analysis of the DC membrane indicated that functional stroma had not established. A few adherent foci were observed, but these cells did not support hematopoiesis. Their identity has not been established, but they resemble macrophages morphologically.

Myeloid progenitors also survive upon implantation of DC in vivo into the peritoneal cavity of mice,[30,31] further substantiating the role of soluble mediators in the maintenance of selected hematopoietic populations. The factor-dependent survival of various long-term hematopoietic lines also substantiates this view. Greenberger and colleagues described a permanent progenitor line that was dependent on factor(s) present in WEHI-3–conditioned medium. This line was multipotent as it could generate neutrophils, basophils, mast cells, and erythroid cells.[32] Growth of factor-dependent cell lines was also reported by Dexter et al.[33] and Nagao et al.[34] Seemingly contradictory results from studies of long-term cultures from hamster marrow indicated that neither an adherent layer nor an exogenous factor addition was required for progenitor cell survival in vitro. As noted by those investigators, however, cell survival in that system may have been due to greater sensitivity to factors present in the serum used or the production of mediators by endogenous cell populations.[35]

Additional indirect evidence for the dependence of cells in DCs on soluble mediators was obtained in experiments in which hematopoietic cells were simultaneously seeded into DCs and onto the underlying stroma. Very few hemopoietic cells were recovered from DCs under those conditions, and progenitor cell numbers had declined markedly. That hematopoiesis had established in association with the adherent layer suggests that those hematopoietic cells closest to the stroma had used the factors produced by it, leaving only low amounts available to the cells in DCs. This may indicate that localized hematopoietic microenvironments exist in vivo and that mediators produced by the stromal cells were used by the hematopoietic cells closest to them.[36] Thus, although some mediators could potentially diffuse longer distances, they indeed may function as short-range molecules. This

Table 3. B Lymphopoiesis in Primary LBMC Requires Stromal Cell Contact

Parameter 4 Weeks Postinitiation	Growth Conditions of Nylon-Wool-Passed Bone Marrow			
	Experiment	DC Over MPA LBMC Stroma	Experiment	Direct Seed on MPA LBMC Stroma
Cell No. (relative change over 10^5 seeded)	1	0	1	$1.1 \times 10^6 \pm 0.5$ (↑11)
	2	0	2	$4 \times 10^5 \pm 0.2$ (↑4)
% 14.8 (relative change in absolute no.)	1	0	1	5 (↑5)

	2	0	2	19.1 (↑76)

Nylon-wool-passed bone marrow (10^6) seeded into DCs placed over MPA-purified LBMC stroma or directly onto MPA-purified LBMC stroma under LBMC conditions. Assays were performed 4 weeks postseeding. Numbers indicate mean ± SD. Percentage of 14.8+ cells in experiments 1 and 2 in the NW reseed population were 10 and 6.5, respectively. Percentage of $sIgM^+$ cells in reseed population in experiments 1 and 2 in the NW reseed population were 1 and 0, respectively. Data expressed as mean ± SD. Each well (three per condition) counted individually, but cells were pooled for cell surface staining.

could further explain why it is difficult to detect factors in supernatant medium from ongoing long-term bone marrow cultures,[11] since all that is produced is bound by the hematopoietic populations in the cultures.

Although hematopoiesis did proceed in DCs under MBMC conditions, blood cell differentiation is not necessarily independent of close stromal cell associations. Indeed, the results we present argue that such associations are required, since the number of cells and progenitors was always greater in parallel cultures in which cells were seeded onto stroma. The inability of the DC B cell precursor to differentiate into B lymphocytes in DC under LBMC conditions further supports this position. These associations could be mediated by direct contact between hematopoietic and stromal cells. Alternatively, developing blood cells may require interactions with growth factors presented within the context of the hematopoietic microenvironment,[37] such as by their attachment to components of the extracellular matrix.[38] Thus, DCs may permit short-term, low-level hematopoiesis in the absence of optimal conditions. Nevertheless, the DC approach is useful for demonstrating the influence of factors on particular lineages and maturational states.

The demonstration of a B cell precursor in DCs makes this point particularly evident. A B cell precursor was present in DCs in MBMC medium 3 weeks postseeding. That mature B and pre-B cells are not present under these conditions[12] suggests that a factor that acts on B cell precursors exists. Whether this putative mediator promotes survival of these populations or their self-renewal cannot be determined from these experiments. How it might relate to the pre-B cell differentiation factor secreted by stromal cell line S17 is also unknown. The latter agent potentiates the expression of the 14.8 antigen and cytoplasmic μ heavy chains in bone marrow B cell progenitors in a 24-hour short-term assay.[39] Different mediators, whose actions affect distinct B lineage target cells, may exist. Ultimately, identification of the factor that maintains B cell precursors in DC will be dependent on replacing the underlying stroma with a conditioned medium that can be characterized.

Clonogenic Hemopoietic Precursors in Bone Marrow Transplantation

By H.A. Messner, J.E. Curtis, M.D. Minden, D. Tritchler, G. Lockwood, T. Takahashi, J. Lepine, N. Jamal, M. Tweeddale, and U. Wandl

Multilineage and single-lineage hemopoietic precursors were studied in 102 bone marrow transplant recipients and their respective donors to determine their contribution to clinical outcome as measured by time to engraftment and survival. The patient population was heterogenous with respect to diagnosis and disease status. They included individuals with acute myeloid leukemia (AML), chronic myeloid leukemia (CML), acute lymphoblastic leukemia (ALL), aplastic anemia, and a few other hematopoietic malignancies. The frequency of various clonogenic precursors in the normal donor population varied considerably. The data yielded a symmetrical distribution. In contrast, most bone marrow transplant recipients presented with significantly reduced numbers of clonogenic cells before transplantation, resulting in skewed distribution profiles. Serial studies of recipients demonstrated a significantly lower than normal level of clonogenic precursors even 3 and 4 years after transplantation. The median values and distribution profiles approximated those observed before transplantation but did not return to measurements obtained for normal donors. Patients with ALL deviated from this pattern. The median values and distribution profiles of clonogenic precursors before transplantation approximated the pattern of normal donors. The frequency of clonogenic progenitors after transplantation, however, remained significantly lower than that of their respective donor or pretransplant values. Cell cycle studies performed after normalization of peripheral blood hematopoietic parameters demonstrated for most recipients that a higher than normal proportion of multipotent cells was in S-phase ($P = .011$). By univariate and multivariate approaches, clonogenic precursors and clinical parameters were assessed for their contributions to clinical outcome as measured by time to engraftment and survival time. The number of nucleated cells in the transplant inoculum contributed to survival independent of other risk factors. Patients with a higher cell load had a higher probability of surviving than did patients with a lower cell concentration in the transplant inoculum ($P = .042$). The frequency of clonogenic precursors in the transplant inoculum altered neither survival nor time to engraftment. The time to engraftment was significantly influenced by the frequency of clonogenic megakaryocyte precursors (CFU-M) observed in recipients prior to transplantation ($P = .003$). Patients with high values engrafted faster than did patients with a low frequency of CFU-M. This was independent of both diagnosis and disease status of the patients at time of transplantation.

CLINICAL BONE MARROW transplantation (BMT) has developed into a treatment modality with curative potential for patients with hematopoietic malignancies and other bone marrow deficiency disorders. Most long-term disease-free survivors are able to maintain production of peripheral blood cells in normal quantity. Despite this ability, the frequency of early hemopoietic precursors may not return to normal. This was suggested by studies reporting a low frequency of granulocyte-macrophage and erythroid progenitors in recipients after transplantation.[1,2]

The objective of this study was to monitor pluripotent precursors (CFU-GEMM) and progenitors committed to erythropoiesis (BFU-E), megakaryocytopoiesis (CFU-M), and granulocyte-macrophage production (CFU-C) in BMT recipients before and serially after transplantation as well as to assess their cell cycle status. In addition, the concentration of clonogenic cells was determined in each transplant inoculum. By univariate and multivariate approaches, the culture data were analyzed in conjunction with clinical parameters to determine their contribution to the outcome of the patients as measured by time to engraftment and survival time.

MATERIALS AND METHODS

Patients

One hundred two consecutive patients undergoing allogenic BMT at the Ontario Cancer Institute between March 1980 and January 1984 and their respective HLA-identical donors gave informed consent to be entered into the study (Table 1). The preparative regimens were described previously in detail.[3] In brief, patients with acute myeloid leukemia (AML) and chronic myeloid leukemia (CML) were prepared with a continuous infusion of cytosine arabinoside at a dose of 100 mg/m^2/day for 5 days, followed by cyclophosphamide at 60 mg/kg/day for 2 days and total body irradiation (TBI) at a mid-plane dose of 500 cGy delivered at 50 to 85 cGy/min by a single cobalt source.[4] Patients with acute lymphoblastic leukemia (ALL) received 2 mg Vincristine intravenously (IV), 200 mg of predisone/day for 5 days, 30,000 U L-Asparaginase per day for 5 days, cyclophosphamide 60 mg/kg/day for 2 days, and a single fraction of TBI at 500 cGy. Patients with aplastic anemia were treated with cyclophosphamide at 50 mg/kg/day for 4 days followed by a single dose of 300 cGy TBI. Attempts were made to transplant at least 3×10^8/kg nucleated cells of the recipient's body weight.

Two different consecutive regimens for graft-*v*-host disease (GvHD) prophylaxis were used. The first 34 patients were treated with the standard methotrexate regimen until day 100.[5] The following 68 patients received Methotrexate on days 1, 3, 6 and 11 and prednisone at a daily dose of 40 mg/m^2 starting on day 10. This dose was sustained until day 40 and subsequently tapered. Sixty-six patients transplanted from March 1980 to December 1982 who developed acute GvHD of grades II through IV were treated with

various regimens including high-dose predisone and/or antithymocyte globulin (ATG). Thirty-six patients transplanted since 1983 who developed acute GvHD received therapy with cyclosporine A (CyA). The initial dose of CyA was either 12.5 mg/kg/day orally or 5 mg/kg/day IV delivered in two divided doses at 12-hour intervals.[6] Subsequent doses were adjusted to maintain normal creatinine values and CyA levels between 50 and 300 μg/L. Patients with chronic GvHD were treated with azathioprine and prednisone. The median follow-up of the entire group was 38 months, with a minimal follow-up of 18 months at the date of the last follow-up.

Preparation of Cells

Bone marrow samples were obtained from transplant recipients prior to their ablative therapy and serially after transplantation on day 14, after 1, 2, 3, 6, and 12 months, and then annually. The samples were aspirated into heparinized syringes. The donor specimen consisted of 5 to 10 cc of bone marrow obtained as part of the transplant inoculum.

Cell Culture

Bone marrow samples were cultured as previously described[7,8] in Iscove's modified Dulbecco's medium (IDMEM, GIBCO, Grand Island, NY) supplemented with 0.9% methylcellulose (Dow Chemical, Midland, MI), 5×10^{-5} mol/L 2-mercaptoethanol (Sigma, St Louis), 5% medium conditioned by phytohemagglutinin-stimulated leukocytes (PHA-LCM, PHA, HA 15; Wellcome Diagnostics, Dartford, England), and 30% human plasma obtained from a patient with severe aplastic anemia. The latter contained an equivalent of 2 to 3 U/mL erythropoietin (EPO). The culture plates were scored after 14 days by inverted microscopy for the presence of multilineage colonies, erythroid bursts, and megakaryocyte and granulocyte-macrophage colonies.

Cell Cycle State Analysis

Bone marrow samples of 17 normal BMT donors and 29 BMT recipients at least 6 months post engraftment were examined to determine the proportion of clonogenic precursors in S-phase by preincubation with tritiated thymidine (^{3}HTdR) as described by Minden et al.[9]

Statistical Methods

Statistical analysis of counted data, such as colony numbers, was performed on the square-root transformation of the actual data value. This transformation resulted in a more symmetrical distribution than did the actual colony counts. It was also used when the prognostic value of colony counts was assessed in the Cox regression model described below. The Mann-Whitney test[10] was used for simple comparisons between groups. Pearson product-moment correlations[10] were computed on appropriately transformed data.

The prognostic value of cell culture and clinical parameters for time to engraftment and survival were evaluated by univariate and multivariate analysis. For the purpose of this study, survival time is defined as the time from BMT to death or to the date of last follow-up. Time to complete engraftment of all three hematopoietic lineages is defined as the time from BMT to the time when >50,000 platelets and reticulocytes and >1,500/μL neutrophilic granulocytes of peripheral blood were observed. Time to partial engraftment is defined as the time from BMT to the time when cells of at least two lineages were present in the above-stated frequency. Seventy-nine patients (77%) surpassed the stated lower limits for all three lineages, 95 (92%) surpassed the limits for at least two, and 100 (97%) surpassed the limits for at least one of the hemopoietic lineages. The analysis of time to complete or partial engraftment included only the respective subsets of patients who ultimately fulfilled the criteria of complete or partial engraftment as defined above. This approach was chosen to avoid violation of the statistical assumption that the time to engraftment was independent of the censoring time for engraftment (in this case, time to death).

The examined donor parameters included the number of nucleated cells and number of CFU-GEMM, BFU-E, CFU-M, and CFU-C in the transplant inoculum. In addition, these values were also expressed as cells transplanted per kilogram of the recipient's body weight. Each recipient was characterized by the frequency of these clonogenic precursors and the number of reticulocytes, platelets, and neutrophilic granulocytes prior to transplantation. In addition, clinical parameters of the recipient were taken into consideration. These included age, sex, weight, diagnosis, and risk as based on the disease status at the time of transplantation. The good-risk group included patients with AML and ALL in first remission, patients with CML in first chronic phase, and patients with aplastic anemia. The poor-risk group included patients with AML and ALL in relapse and subsequent remission, patients with CML in accelerated phase, blast crisis, or second chronic phase and the patients with multiple myeloma, lymphoma, and idiopathic thrombocythemia. The latter subgroup of various hemopoietic disorders was included since these patients presented with advanced disease. Each recipient was also assessed for the presence of GvHD.

The influence of each attribute was initially evaluated in a univariate analysis. Continuous variables were examined using the Cox regression method.[11] Categorical variables were assessed using log-rank (Savage) statistics.[12] Contributions to engraftment and survival by attributes that were significant were displayed by Kaplan-Meier plots.[13]

Multivariate analyses were performed to determine whether or not effects of cell culture parameters observed by univariate studies were sustained when tested in conjunction with clinical parameters. For this purpose, stratified and unstratified multipredictor Cox regression models[11] were constructed to control for the effects of prognostic factors.

RESULTS

Clinical Data

Details about age, diagnosis, and disease status of all patients at the time of transplantation are listed in Table 1. In addition, the number of surviving patients and the relapse rates are presented for each subgroup. The Kaplan-Meier plot of the overall survival of the whole group is shown in Fig

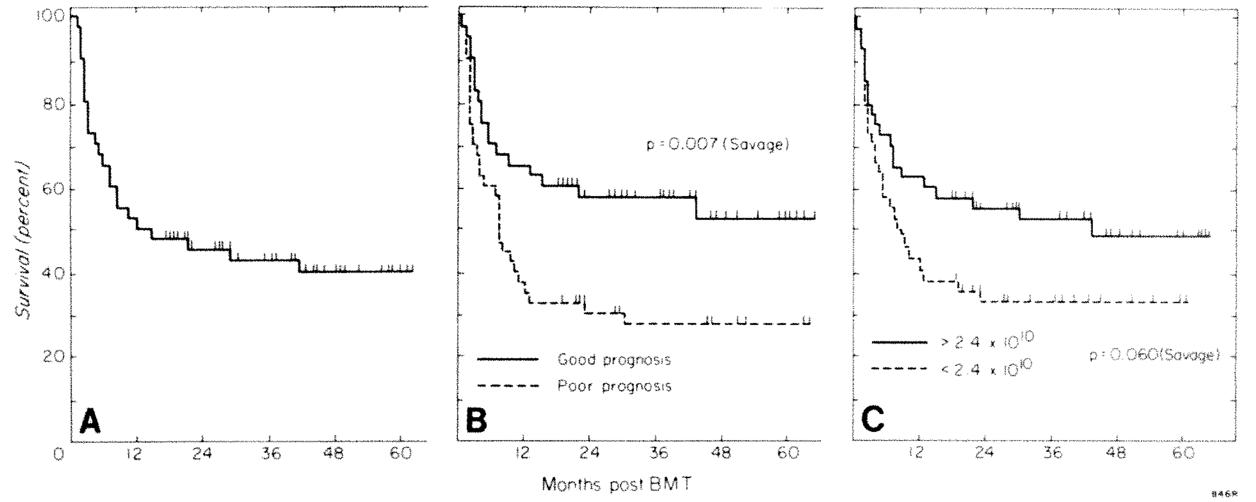

Fig 1. (A) Overall survival curve for all patients (Kaplan-Meier). (B) Survival curves for low-risk and high-risk disease as defined by disease status at the time of transplantation. (C) Survival curves of patients transplanted with less or more than 2.4 × 10^{10} mononuclear cells.

1A. The subgroup of 42 patients with early well-controlled leukemia included 19 with AML and 9 with ALL in first remission as well as 14 with CML in first chronic phase. Twenty-four (57%) are alive and free of relapse at the end of the study. Two patients with AML and two with ALL have relapsed. None of the surviving patients with CML have shown signs of disease recurrence.

The 41 patients with more advanced leukemia included 8 with AML and 10 with ALL in relapse or subsequent remission as well as 22 with CML who presented either in accelerated phase (17 patients), blast crisis (5 patients), or second chronic phase (1 patient). Nine patients are alive and have remained free of relapse (23%) (Fig 1B); ten (24%) have relapsed.

The small subgroup of 5 patients with other hematopoietic malignancies included 2 patients with lymphoma, 2 patients with multiple myeloma, and 1 patient with idiopathic thrombocythemia. One patient with lymphoma remains alive and disease-free; both patients with myeloma have relapsed; one is still alive on conservative therapy.

Eight of the 14 patients transplanted for severe aplastic anemia are alive; all have normal peripheral blood values. Forty-four of the entire group of 102 patients are alive (Fig 1A). The causes of death in the remaining 58 were related to recurrence of the original hematopoietic malignancy in 19%, to infections alone in 15%, and to GvHD alone in 12%. The majority (44%) succumbed to a combination of GvHD and infections. Other causes of death (8%) included poor engraftment or early rejection, severe hemorrhagic complications, and therapy-related central nervous system (CNS) toxicity. 19 patients had infections associated with development of a fatal interstitial pneumonitis. Three additional patients developed clinical and histologic features of bronchiolitis obliterans.

Bone Marrow Culture Studies

Clonogenic precursors in transplant inoculum. Each BMT inoculum was assessed for the number of mononuclear cells and the frequency of clonogenic hematopoietic precursors. The frequency of CFU-GEMM, BFU-E, CFU-M, and CFU-C per 2 × 10^5 mononuclear cells varied considerably from donor to donor. The distribution profiles for clonogenic cells of the donor population showed nearly symmetrical patterns with similar mean and median values. Median values are listed in Table 2. The culture data were used to calculate the number of clonogenic cells for each transplant inoculum and the number of clonogenic cells transplanted per kilogram of the recipient's body weight (Table 3). Again, a considerable patient to patient variation was observed.

†Range.

Clonogenic cells in bone marrow samples of recipients before transplantation. Bone marrow samples of BMT recipients were obtained before administration of the preparative regimens and examined for their ability to form multi-lineage and single-lineage colonies. The distribution profiles for CFU-GEMM, BFU-E, CFU-M, and CFU-C were skewed toward lower colony frequencies. Their median values were significantly lower when compared with the respective values of the donor population (Table 2).

The data were also analyzed separately for each disease group. Patients with AML, CML, and aplastic anemia showed low median values for CFU-GEMM, BFU-E, and CFU-M (range of P values .00001 to .05, Mann-Whitney). The median CFU-C value was only significantly lower than controls for patients with aplastic anemia (P = .00001, Mann-Whitney). In contrast, median colony values for patients with ALL approximated counts of the normal donor population (range of P values .07 to .34, Mann-Whitney).

Clonogenic cells after transplantation. Only a few colonies were identified in bone marrow samples obtained 14 days after transplantation. Predominance of a specific colony type emerging early was not observed. In particular, the frequency of multilineage colonies was not increased in preference to single-lineage colonies. Sequential follow-up demonstrated an increase of all hemopoietic colony types. Normal colony numbers were only occasionally observed, however, even after follow-up periods of >3 years (Table 2). Colony formation in BMT samples obtained from most BMT recipients was reduced to 20% to 40% of values determined for the BMT donor population. The frequency distribution and median values of the entire group 1 year after transplantation approximated the median values of the recipients before transplantation (range of P values .11 to .84, Mann-Whitney). The values remained significantly lower when compared with the respective donor parameters (all P values = .00001, Mann-Whitney). The significant difference from donor values was confirmed when subgroups of patients with AML, CML, and ALL were analyzed individually (range of P values .0001 to .0052). The available sample size for patients with aplastic anemia was too small for an appropriate analysis. The values of clonogenic cells were reduced independent of continuing immunosuppressive therapy. This was demonstrated by examining the subgroup of ten patients that had not received any further immunosuppressive therapy after completion of their prophylactic GvHD regimens. The hematopoietic parameters of this subgroup and of their respective donors prior to transplantation were comparable to those of patients under further medication. The data are listed separately in Table 2 and do not show any difference when compared with those of the whole group.

Cell cycle analysis post-BMT. The proliferative status of precursor populations after transplantation was examined by assessing their cycle state using the ^{3}HTdR suicide technique (Fig 2) and compared with that of normal controls. In normal bone marrow specimens 65% to 95% of CFU-GEMM (median 80%) survived preincubation with ^{3}HTdR. In contrast, samples of BMT recipients tested after normalization of their peripheral counts yielded greater variability in the proportion of surviving CFU-GEMM. The values ranged from 8% to 100%, with a median of 60%. The observed distribution of values differed significantly from the normal control group (P = .011, Mann-Whitney). A similar observation was made for the committed progenitors BFU-E, CFU-M, and CFU-C. The proportion of pluripotent progenitors surviving a preincubation with ^{3}HTdR did not differ from the surviving fractions of committed precursors (range of P values .748 to .830).

The cellularity of the tested bone marrow samples as assessed by the number of mononuclear cells per milliliter of

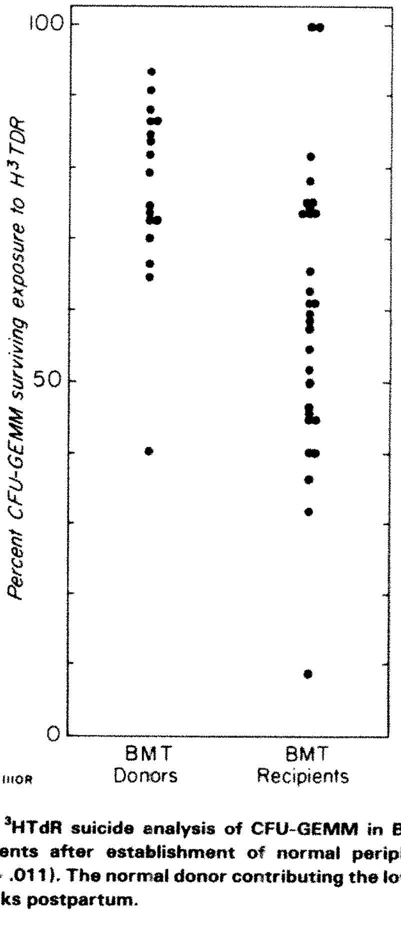

Fig 2. ^{3}HTdR suicide analysis of CFU-GEMM in BMT donors and recipients after establishment of normal peripheral blood values (P = .011). The normal donor contributing the lowest values was 4 weeks postpartum.

Table 4. Influence of Clonogenic Cells in BMT Inoculum and Bone Marrow Samples of the Recipients Before Transplantation

Attributes	Time to Engraftment	Survival

aspirate did not differ for the donor and recipient population ($P = .528$, Mann-Whitney).

These data confirm that nearly all available clonogenic cells are involved in the ongoing production of blood cells. Thus, bone marrow reestablished after BMT appears to function like a marrow under stress without displaying a reserve of resting precursors.

Analysis of Parameters Influencing Time to Engraftment

Time to engraftment. Culture parameters and clinical attributes were examined separately for their influence on time to engraftment. The respective P values are listed in Table 4. The presence of GVHD was the only clinical parameter significantly correlated with the time to engraftment. Patients without GvHD engrafted faster than did patients with GvHD ($P = .009$, Savage). The data are shown in Fig 3A. Neither diagnosis ($P = .254$, Savage) nor disease status ($P = .847$, Savage) of the patients were significant.

Of the culture parameters examined, only the frequency of CFU-M in the recipient before administration of the preparative BMT regimen was significantly related to the time to engraftment ($P = .003$, Cox). Patients with higher CFU-M values before transplantation engrafted significantly faster than did patients with low CFU-M values. The data are displayed as Kaplan-Meier plots comparing the subgroup of patients that formed more than the median number of megakaryocyte colonies in comparison to patients with a colony frequency below the median (Fig 3B). The correlation between CFU-M and time to engraftment remained significant even if patients with ALL who represented a subpopulation with higher CFU-M values were excluded from the analysis ($P = .028$, Savage).

The concentration of CFU-M in recipient marrow before transplantation also predicted the reemergence of platelets and reticulocytes when assessed individually. The frequency of CFU-GEMM and BFU-E was correlated with the time to

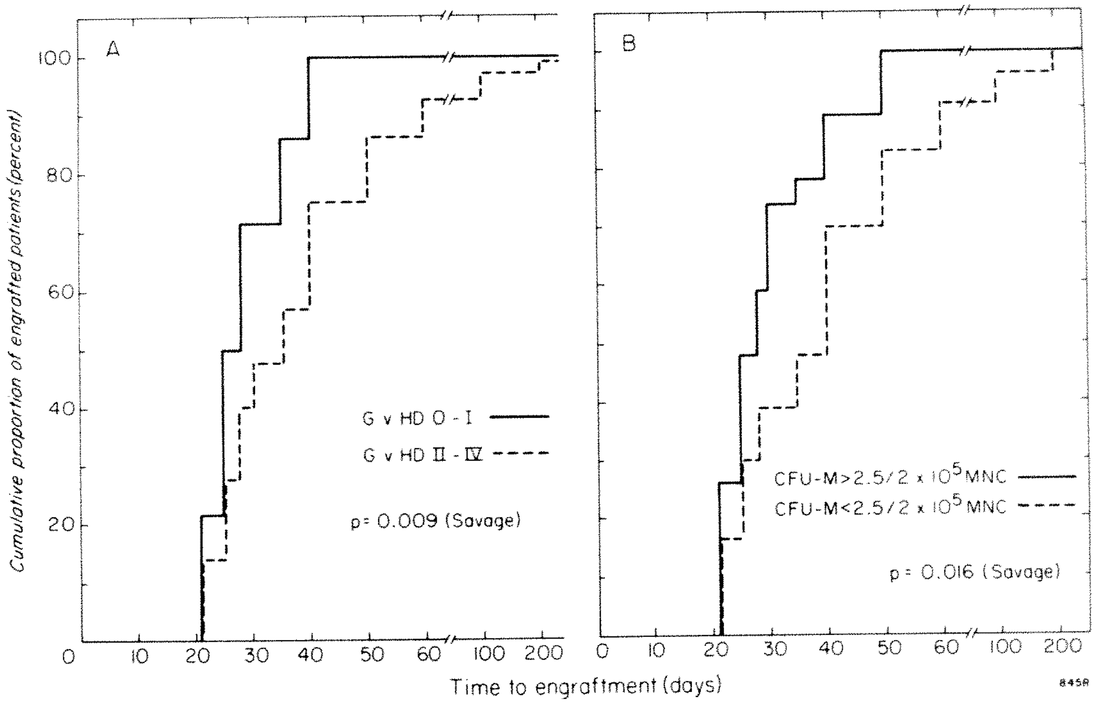

Fig 3. **(A) Time to engraftment for patients with GvHD grades 0 to I and II to IV. (B) Time to engraftment for recipients who formed <2.5 or >2.5 megakaryocyte colonies for 2 × 10^5 mononuclear cells in bone marrow samples obtained before transplantation.**

recovery of reticulocytes ($P = .023$ for CFU-GEMM, and $P = .012$ for BFU-E, Cox), but not of other lineages. The data were further analyzed using multi-predictor Cox regression models to determine whether there was a significant interaction between CFU-M and GvHD and to test whether the inclusion of clinical parameters in the model negated the influence of CFU-M.

First, a regression model including age, sex, and weight of the recipient, pre-BMT frequency of CFU-M, occurrence of GvHD, and an interaction between CFU-M and GvHD was examined. The influence of CFU-M ($P = .002$) and GvHD ($P = .018$) on the time to engraftment was sustained independent of the clinical parameters. The interaction between CFU-M and GvHD was also significant ($P = .018$). The interaction indicated that the influence of CFU-M was greater for patients with GvHD.

Second, three regression models were constructed to test whether diagnosis or previous therapy, as measured by disease status, affected the significance of either CFU-M or GvHD. These models included the same parameters as above but, in addition, were stratified by (a) diagnosis, (b) disease status, and (c) both. In each of the three models CFU-M ($P = .0015$ to $.0069$) and GvHD ($P = .013$ to $.02$) remained strongly significant. The multipredictor Cox regression results indicate that both CFU-M and GvHD are significantly related to time to engraftment, independent of the other clinical parameters tested.

Analysis of parameters influencing survival time. Similar studies were performed to assess the influence of the same cell culture and clinical parameters on survival time (Table 4). Again all parameters were initially assessed alone and subsequently in conjunction with each other using the Cox regression model.

The univariate analyses showed that survival was significantly influenced by the disease status at the time of transplantation. Patients with acute leukemia in first remission, chronic-phase CML, and aplastic anemia had a greater probability of surviving when compared with patients with more advanced disease ($P = .007$, Savage). The data are displayed as Kaplan-Meier plots in Fig 1B. No other clinical parameter was significant.

Of the culture parameters, the frequency of clonogenic precursors in recipients prior to transplantation and number of clonogenic progenitors in each transplant inoculum were not predictive of survival. In contrast, the total number of nucleated cells in the transplant inoculum made a significant contribution ($P = .042$, Cox). Patients transplanted with a larger inoculum had better overall survival than did patients who had received a lower cell load. For the purpose of a visual display as Kaplan-Meier plot, patients were subdivided into a group below and above the median number of transplanted nucleated cells (Fig 1C). A correlation with survival was not observed when the number of nucleated cells transplanted per kilogram of the recipient's body weight was used for the analysis ($P = .185$, Cox).

A multivariate analysis was performed to test the influence of the total number of nucleated cells in conjunction with other parameters. The Cox regression model included age, sex, weight, and was stratified by risk group as defined by disease status. The influence of the total number of nucleated cells in the transplant inoculum on survival was sustained ($P = .042$) independent of the contribution of the other parameters.

DISCUSSION

The reestablishment of hemopoiesis after BMT is a multifactorial process that involves a number of donor and host parameters. We examined clonogenic hematopoietic precursors in the host before and serially after BMT and determined their quantity in donor-derived BMT inocula. The frequency of clonogenic progenitors in bone marrow samples collected from most BMT recipients before administration of the ablative pre-BMT regimen was significantly lower than that observed for the respective donor values. The resulting frequency distributions were skewed toward low levels. Only BMT recipients with ALL had normal progenitor numbers and distribution profiles.

Colony formation after transplantation did not return to the level of their respective donors but approximated the low pre-BMT values. The data obtained post-BMT for patients with ALL were indistinguishable from results of recipients with other primary diseases. These data suggest that hematopoiesis after transplantation is maintained by a reduced number of clones. This view is supported by animal experiments using retrovirus-transduced stem cells for reconstitution of lethally irradiated mice. Lemischka et al[14] showed that animals were repopulated by clones derived from as few as 1 or 2 stem cells. The increased proportion of pluripotent precursors in S-phase therefore reflects attempts to compensate for a decreased bone marrow reserve.

Our data describing a reduced frequency of pluripotent and committed precursors confirm data previously reported for CFU-GM and BFU-E by Arnold et al[1] and CFU-GM by Li et al.[2] They differ from observations by Norrie et al,[15] indicating return to normal values of CFU-GM, CFU-E and BFU-E in their series of 29 patients. The reason for this difference is not clear. It may relate to differences in the culture technique, expression of the data as number per volume of bone marrow or blood rather than as plating efficiency. Differences in the preparative regimen may affect the regenerative capacity of the bone marrow by influencing for instance the stromal support.

In addition, as suggested by Li et al,[2] one may postulate the suppression of clonogenic precursors after BMT by cellular or molecular mechanisms. We removed E rosette-positive cells from four bone marrow samples obtained after BMT and observed a significantly greater than anticipated increment in the plating efficiency of one specimen.

The observation that the number of nucleated cells may influence survival of the examined patient population remains of practical interest since it is technically feasible to increase the number of transplanted cells. The importance of the size of the BMT inoculum for sustained and stable engraftment and reestablishment of a normal reserve has been well documented in murine hemopoiesis. Serial retransplant experiments demonstrated that only bone marrow of primary transplant recipients who had received a large marrow inoculum was able to repopulate secondary hosts.[16,17]

The importance of cell number in clinical transplantation was previously demonstrated for aplastic anemia by Storb et al,[18] who reported in an analysis of 73 patients a higher rate of graft rejection for patients transplanted with 3 × 10^8 nucleated cells/kg. In addition, Ringden and Nilsson[19] demonstrated that patients with GvHD had a significantly better chance of surviving if they were transplanted with a higher total cell dose. Future clinical studies are necessary to determine whether a larger BMT inoculum will improve the bone marrow reserve in BMT recipients.

Investigators have addressed the question of whether time to engraftment is related to the size and cellular composition of the transplant inoculum. Niederwieser et al[20] showed for 50 patients with acute or chronic myeloid leukemia that a negative nonlinear correlation existed between the number of transfused cells and the duration of leukopenia. Faille et al[21] demonstrated a correlation between the number of CFU-GM and the time to recovery of neutrophils for ten patients with aplastic anemia. A similar observation was made by Spitzer et al[22] for hematopoietic recovery following autologous BMT. In contrast, Torres et al[23] were unable to identify a relationship between the number of transplanted CFU-GM and recovery of peripheral granulocytes in a series of 16 patients transplanted for acute leukemia. Similar results with respect to the total cell number, CFU-GM and CFU-E dose were observed by Atkinson et al.[24]

In our own study, time to engraftment was not correlated with any one of the cell populations in the transplant inoculum. We observed, however, that time to engraftment was significantly influenced by two host-related parameters. First, the development of GvHD, or possibly the therapy for GvHD, played a significant role in the delay of engraftment. Second, the frequency of CFU-M in the recipient before administration of their preparative regimen reflected the speed of recovery of all hematopoietic lineages. This correlation is upheld independent of diagnosis or disease status at the time of transplantation.

It was surprising that CFU-M in the host before BMT reflected the time of bone marrow recovery more accurately than did the pluripotent precursor CFU-GEMM. The reason for this correlation is not currently understood. CFU-M may reflect the behavior of a more primitive progenitor cell population that is essential for engraftment. This view is supported by a report that CFU-M in murine hematopoiesis and day 14 CFU-S bear similar surface determinants detected by the monoclonal antibody denoted as Qa-M^2,[25] whereas the antigen is not expressed by day 7 CFU-S considered to be more mature. Alternatively, CFU-M may represent a precursor population that requires optimal growth support in vivo. Their frequency may reflect the functional status of the growth-supporting hematopoietic microenvironment of the host and its ability to promote the proliferation of transplanted precursors. This hypothesis is consistent with the observation that BMT recipients usually establish erythropoiesis and granulopoiesis before platelets are produced at an adequate rate.

Examination of the role of CFU-M in the host is necessary. A preliminary study has indicated that the host may produce stimulatory molecules for CFU-M and, to a lesser degree, for other clonogenic precursors shortly after receiving the preparative regimen.[26] These can be readily identified in the plasma of transplant recipients and may serve as an additional measurement to examine hematopoietic regeneration after transplantation.

ACKNOWLEDGMENT

We would like to acknowledge the contribution to the care of these patients by Drs A. Smith, C. Shea, G. Fyles, B. Czerkawski, L. Cruz, and the nursing staff of the BMT Unit. Lorraine Dwyer and Dr K. Yamasaki were helpful in the preparation of the manuscript.

High-Dose Intravenous Gamma Globulin Improves Responses to Single-Donor Platelets in Patients Refractory to Platelet Transfusion

By Zella R. Zeigler, Richard K. Shadduck, Craig S. Rosenfeld, Kenneth F. Mangan, Alan Winkelstein, Arsinur Oral, Glenn E. Ramsey, and Rene J. Duquesnoy

Ten patients, with bone marrow failure or malignant disorders, became refractory to platelet transfusions using random, as well as partial or fully HLA-matched, single-donor platelets. To determine its effect on platelet refractoriness, intravenous gamma globulin (IV IgG) was administered at 400 or 800 mg/kg/d for five days, and postinfusion platelet responses were monitored. Platelet transfusion responses following intravenous gamma globulin (IV IgG) were graded as follows: Excellent, 48-hour posttransfusion count > 50,000/μL; good, 48-hour count > 20,000 but <50,000/μL; Fair, increased increment, 48-hour count < 20,000; and failed, no increased increment. Six of ten patients (60%) had improved responses to selected single-donor platelets (two were excellent, three were good, and one was fair). The time to achieve a platelet transfusion count >25,000/μL ranged from one to nine days of IgG therapy. One individual had sustained benefit (>1 year); the remaining responses persisted for 6 to 8 weeks. These results suggest that IV IgG may be useful in the management of platelet refractoriness, especially in patients receiving single-donor platelets.

© 1987 by Grune & Stratton, Inc.

PLATELET refractoriness represents a life-threatening complication in patients with bone marrow failure who have platelet counts <10,000/μL. Poor platelet increments occur in two situations and may have different pathogenic mechanisms. In outpatients with chronic aplasia, poor responses probably reflect alloimmunization.[1-3] In contrast, in febrile patients following chemotherapy-induced aplasia, factors related to infections may contribute to poor transfusion responses. In these patients, it is difficult to discern the relative contribution of allosensitization and/or other factors.

High-dose intravenous gamma globulin (IV IgG) is effective in the treatment of autoimmune thrombocytopenic purpura[4-6] and posttransfusion purpura.[7-10] Results are conflicting, however, in the management of platelet alloimmunization.[11-17] IV IgG is potentially suitable for the management of platelet refractoriness because it has a rapid onset of effect (two to five days) and does not suppress bone marrow.[4-6] We report the beneficial effects of IV IgG in the management of a cohort of platelet-refractory patients.

MATERIALS AND METHODS

Patients. Ten patients who became refractory to platelet transfusion, defined as a one-hour posttransfusion increment of <15,000/μL, participated in this study. All ten had failed to respond to 24 to 110 U random-donor platelets, (administered as 6- to 10-U platelet transfusions) and to platelet transfusions from donors who were HLA-identical, partially matched, or selectively mismatched, for cross-reactive HLA antigens.[18-20] Each patient gave informed consent for participation in this study. The protocol was approved by the Institutional Review Board of Montefiore Hospital, University of Pittsburgh School of Medicine.

The clinical characteristics of the patients are shown in Table 1; four patients (patients no. 1 through 4) had chronic aplastic anemia and became refractory to prophylactic transfusion of selected single-donor platelets. Patient no. 4 developed pneumonia five days after initiation of IV IgG therapy; the other patients with aplasia were afebrile. Three patients (patients 5 through 7) had bone marrow failure due to lymphoma and developed refractoriness to chronic platelet transfusion therapy; one (patient no. 7) was receiving active chemotherapy. The remaining patients failed to obtain platelet responses to transfusion while undergoing induction therapy for acute nonlymphocytic leukemia (ANLL).

Patients varied in the duration of blood support (2 weeks to 3 years) and the number of unit exposures (13 to 735 U). Generalized alloimmunization, as judged by HLA-antibody screening, was detected in eight patients; these patients showed antibodies against >75% of screening cells. Six had fever, two had enlarged spleens, and 1 (patient no. 5) had undergone splenectomy earlier in her treatment course. HLA-identical platelets were available and ineffective in six of the ten patients. Five had gastrointestinal (GI) bleeding (melena, hematemesis, or rectal bleeding), and one suffered limited hemorrhage into the CNS during the time of study. Three patients (patients no. 2, 5, and 6) who failed to respond died of uncontrolled bleeding.

IgG infusion. All patients received IgG (Sandoglobulin) as an IV infusion over six to eight hours at a dose of 400 mg/kg/d for five days. This dose was chosen to correspond to that recommended for the treatment of immune thrombocytopenia purpura. If no response occurred during the five-day course of therapy, the dosage was increased to 800 mg/kg/d until a posttransfusion platelet count ≥25,000/μL was obtained or for an additional five days. Single-donor platelets were given within one to ten hours of the IgG infusion if the platelet counts were <20,000/μL. Random-donor platelets were not given unless the patient was actively bleeding and single-donor platelets were ineffective.

Definition of platelet responses. One-hour posttransfusion platelet counts were performed by chamber analysis using the method of Brecher and Cronkite.[21]

Responses to single-donor platelets were graded as follows: Excellent, increased increment, 48-hour count >50,000/μL; good, increased increment, 48-hour count > 20,000 but < 50,000/μL; fair, increased increment, 48-hour count <20,000/μL; and failed, no increased increment.

For single donors that were used repetitively for a given patient, the degree of HLA match to the patient was determined. This was based on HLA-A and HLA-B loci and published cross-reactivity information.[18-20] The match categories were defined as follows: A

Table 1. Platelet Refractory Patients: Clinical Characteristics

Sex	Age	Diagnosis	Blood Support (mos)	Blood or Platelets Administered (U)	HLA Screen No. Positive/ No. Screening Cells	Temperature $>100°F$	Spleen	A-match Donor
M	14	Chronic aplastic anemia	5.0	735	+ 28/30	N	NP	NA
M	57	Chronic aplastic anemia	13.0	149	+ 40/48	N	NP	NA
M	59	Chronic aplastic anemia	1.0	115	+ 29/30	N	NP	Failed
F	56	Chronic aplastic anemia	5.0	191	+ 17/20	Y	NP	NA
F	62	Lymphoma	17.0	315	+ 21/48	N	Splenex	Failed
F	53	Lymphoma	15.0	477	+ 21/24	Y	Enlarged 6 cm	Failed
F	60	Lymphoma	1.0	59	+ 36/48	Y	Enlarged 3 cm	Failed
M	24	Acute aplasia ANLL	3.5	156	+ 36/48	Y	NP	Failed
F	60	Acute aplasia ANLL	1.0	174	+ 27/30	Y	NP	Failed
F	77	Acute aplasia ANLL	0.5	13	+ 10/48	Y	NP	NA

N, no; Y, yes; NP, not palpable; Splenex, splenectomy; NA, not available.

match, HLA-A and HLA-B antigen identical; B match, three donor antigens matched and the fourth unknown or cross-reactive, or two donor antigens matched and the third and fourth unknown or cross-reactive; C match, three donor antigens matched and one mismatched; and D match, two or more donor antigens mismatched.

Platelet-associated IgG levels. Platelet-associated IgG levels were measured by the immunodiffusion assay of Morse et al.[22] Levels were monitored before and during the administration of IgG, and at times before the next transfusion, when the platelets were $<15,000/\mu L$. This was done so that changes would not be due to an increase in the platelet count.

RESULTS

Platelets from random donors were without benefit in six patients after administration of IV IgG. The results obtained with selected single donors are summarized in Table 2. The total amount of IV IgG administered varied from 2.0 to 6.0 g/kg. One patient (no. 4) continued to receive booster doses of 800 mg/kg before each platelet transfusion because of the fair response and the clinical judgment that continued IgG improved platelet increments. The other patients received only the initial course of IgG.

In this series, six patients had improved responses to platelet transfusion of selected single-donor platelets. Two of the responses were excellent, three were good, and one was fair. The time to a transfusion-related platelet count of $>25,000/\mu L$ ranged from one to nine days. In patients in whom the duration of response could be evaluated, most responses persisted from 6 to 8 weeks; however, one patient (patient no. 4) has had excellent responses to platelet transfusions in >1 year of observation.

The best response is summarized for patient no. 4 (Table 3), who had been supported by selected single donors for 5 months because of failure to respond to 30 U random-donor platelets. On three successive days, transfusion of platelets from donors that had been effective failed to provide adequate increments. The patient was admitted (October 10, 1984) for IV IgG in an attempt to improve platelet support. The first dose of IgG was administered, followed by platelet transfusion from donor no. 4, which provided a transfusion increment of $40,000/\mu L$, but a markedly shortened survival (the 24-hour count was $<16,000/\mu L$). Platelets from donor no. 4, on the seventh day of IV IgG, survived better, with a 48-hour count of $39,000/\mu L$. Improved increments are shown in Table 3 for each of the three donors used for this patient during the platelet refractory period.

Responses to platelets from single donors who were known to be effective before the refractory state were retested after IgG in three patients (patients no. 1, 4, and 8). The data from these seven donors is shown in Fig 1. For comparison, the 1-hour posttransfusion increment observed the first time a donor was used for that patient was considered to be 100%;

Table 2. Platelet Transfusion Responses After High-Dose IgG Therapy

Patient No.	Amount of IV IgG Administered (g/kg)	Response	Days to Platelets $\geq 25,000/\mu L$	Duration
1	6.0	Fair	7.0	8 weeks
2	6.0	Failed	—	Died of hemorrhage
3	6.0	Failed	—	Alive (platelets = $1,000/\mu L$)
4	2.0	Excellent	1.0	17 months
5	6.0	Failed	—	Died of hemorrhage
6	2.0*	Failed	—	Died of hemorrhage*
7	5.2	Good	9.0	>6 weeks†
8	2.0	Excellent	3.0	6 weeks‡
9	3.6	Good	5.0	>10 days* Died, refractory leukemia
10	6.0	Good	8.0	>11 days†

*Refused all further therapy.

†Bone marrow recovered.

‡Died of refractory leukemia at 8 weeks.

Table 3. Summary of Patient 4

Donor No.	Date	Platelet Count (μL) Pretransfusion	1-h Posttransfusion
A. Prerefractory period			
1	8/22/84	2,000	75,000
2	7/25/84	9,000	45,000
3	6/19/84	4,000	77,000
4	8/29/84	33,000	96,000
B. Refractory period			
1	10/8/84	5,000	21,000
2	10/9/84	4,000	16,000
3	10/10/84	3,000	15,000
C. Post IV IgG			
1	1/2/85	16,000	112,000
2	11/9/84	33,000	92,000
3	1/15/85	35,000	112,000
4	10/11/84	1,000	41,000
	(day 1 IV IgG)		(24-h < 16,000)
	10/17/84	7,000	70,000
	(day 7 IV IgG)		(48-h = 39,000)

the remaining results are expressed as a percentage of that baseline increment. Following IV IgG therapy, one-hour increments averaged 107.5% ± 16.7% (n = 16) of baseline as compared with 22.8% ± 2.8% (n = 8) in the refractory period of time, $P < .001$. The degree of HLA match between the donor and recipient did not appear to influence the results; improved increments occurred with grades of HLA match ranging from A through D.

Platelet associated-IgG (PA-IgG) levels were measured before transfusion and before and during therapy with IgG. Baseline values were elevated in seven of eight patients (Fig 2) and did not discriminate between responders and nonresponders. In contrast, a correlation was observed between responses and PA-IgG level obtained on days 7 through 15 of IV IgG therapy. In responders, values ranged from 3 to 11.4 fg/platelet; in nonresponders, the PA-IgG values ranged from 12 to 100. Responders showed a decline in PA-IgG; in contrast, nonresponders either showed no change or an increase in their levels.

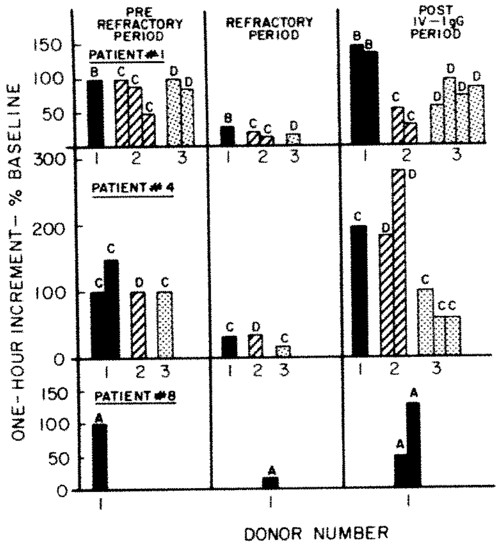

Fig 1. Comparison of one-hour posttransfusion platelet increments after use of selected single donors in prerefractory, refractory, and posttreatment periods in three patients. For comparison, all one-hour increments are expressed as percentage of baseline, (the increment obtained the first time that donor was used). (B through D): grade of HLA match of the donor.

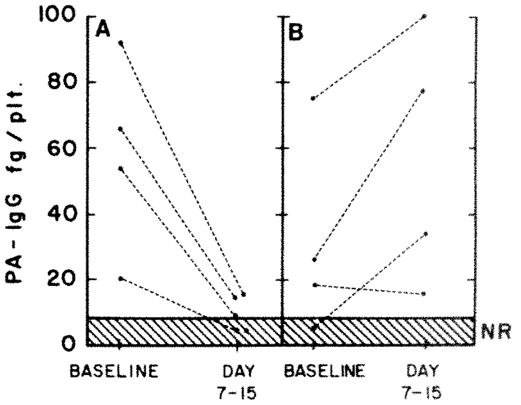

Fig 2. PA-IgG levels before and after IV-IgG treatment. PA-IgG levels were elevated in seven of eight patients prior to treatment (>6 fg/platelet). Repeat PA-IgG levels on days 7 through 15 of therapy were significantly lower in the group of responders as compared with nonresponders. This represented a decline of the levels in responders, whereas nonresponders either showed no change or an increase.

DISCUSSION

Although scattered reports[12-15,17] describe favorable responses to IV IgG in alloimmunized platelet transfusion recipients, the prevailing data are negative.[11,16] Studies by Schiffer et al[11] and Knupp et al[16] indicated no improvement in platelet transfusion responses to IV IgG. Thus, their results differ from those in this study.

From the present data, determination of the reasons for these discrepant results is impossible. Most of the patients reported herein received higher doses of IgG than were used in previous studies. Because the same preparation of IgG was used in both this study and that reported by Schiffer et al,[11] the choice of preparation does not appear to explain the difference. In this study, patients were given platelet transfusions in conjunction with the IgG therapy rather than having platelets administered after a course of IV IgG. Moreover, all the present patients were given the best HLA-matched single-donor platelets available. Further observations will be necessary to determine which, if any, of these differences are important in reversing the platelet-refractory state.

In this series, patients had improved responses to selected single-donor platelets; however, random-donor platelets were tried without benefit. Therefore, this therapy may not improve responses to random platelets in most cases, as has been noted previously.[11] That transfusion responses were restored to HLA-D–matched platelet products suggests that some responses to random products may be anticipated.

Although IV IgG improved responses to transfused platelets in selected patients, the mechanisms involved are unclear. In contrast to immune thrombocytopenic purpura in which data[5] suggest that platelet destruction is due to reticuloendothelial clearance of antibody-coated cells, the mechanism of destruction of allogeneic platelets is not established. Beneficial effects of IV IgG may also result from delayed clearance of sensitized cells. An analogy can be drawn to the findings of Grumet and Yankee,[2] who demonstrated that corticosteroids or splenectomy could improve transfusion increments to HLA- compatible, but not random-donor, platelets in alloimmunized aplastic patients.

The present observations suggest that IV IgG may be able to interfere with antibody coating of platelets. Decreased PA-IgG levels were observed as early as 1 day after institution of IgG therapy (data not shown). This decreased antibody binding continued throughout the study and correlated with response. PA-IgG levels on days 7 through 15 of therapy remained high in nonresponders and fell in responders. These results are similar to those of Becton et al,[13] who noted a decline in surface-associated IgG in two alloimmunized children with aplastic anemia that responded to IV IgG therapy. Moreover, Kekomaki et al,[12] showed that the addition of IgG, but not buffer, reduced alloantibody binding in vitro. Higher drug levels may be important for this mechanism as compared with those necessary to produce reticuloendothelial blockade.

In conclusion, high-dose IgG therapy improved platelet support, with use of single donors, in six of ten platelet-refractory patients. Even though the effect was usually transient (6 to 8 weeks), improved responses may provide valuable time needed for bone marrow recovery following therapy of acute leukemia or aplastic anemia. The use of IV IgG to improve responsiveness to transfused platelets is certainly expensive. In our hospital, 1 g of IV IgG costs \$100.00; thus, the average cost for a single course of 400 mg/kg for five days is ~\$14,000.00. Because of this, IV IgG is not a means of maintaining platelet counts $>20,000/\mu L$ prophylactically; however, this therapy might be considered if a patient is experiencing uncontrollable bleeding and is no longer supportable with single-donor platelet products.

ACKNOWLEDGMENT

We are indebted to M. J. Santicky and A. Welsh for their support in arranging single-donor transfusions for these patients with the transfusion service of Central Blood Bank. We also want to thank B. Kish for her secretarial assistance.

Fibronectin Is Required for Platelet Adhesion and for Thrombus Formation on Subendothelium and Collagen Surfaces

By Eva Bastida, Ginés Escolar, Antonio Ordinas, and Jan J. Sixma

Fibronectin (FN) plays a role in several adhesion mediated functions including the interaction of platelets with subendothelium. We investigated the role of plasma FN in platelet adhesion and platelet thrombus formation under flow conditions. We used two different perfusion models: the annular chamber with α-chymotrypsin–treated rabbit vessel segments, and the flat chamber with coverslips coated with fibrillar purified human collagen type III. Perfusates consisted of washed platelets and washed RBCs, suspended in normal or FN-depleted plasma. Perfusions were carried out for ten minutes at shear rates of 300 or 1,300 s^{-1}. Platelet deposition and thrombus dimensions were evaluated morphometrically by a computerized system. We found that depletion of plasma fibronectin significantly reduced the percentage of total coverage surface and percentage of platelet thrombus, at both shear rates studied, and in both perfusion systems ($P < .01$) ($P < .01$). The dimensions of the platelet thrombi formed in perfusions at high shear rate were also significantly reduced in perfusions carried out with FN depleted plasma ($P < .01$). Addition of purified FN to FN-depleted perfusates restored all values to those measured in the control perfusions. These results indicate that plasma FN is required for platelet aggregate and thrombus formation following adhesion under flow conditions.

PLATELET ATTACHMENT, spreading and aggregation on vascular subendothelium are crucial events in platelet thrombus formation. Several factors are known to regulate these events: physical factors,[1,2] subendothelial components,[3] adhesive proteins,[4] and specific receptors on the platelet membrane.[5]

Fibronectin (FN) is a multifunctional glycoprotein with numerous biological roles. Besides its interactions with platelets, FN is known to promote attachment and spreading of cells on collagenous substrates,[6] and to bind to different types of cells such as fibroblasts,[7] rat kidney cells,[8] and malignant melanoma cells.[9] Recent studies have demonstrated that the Arg-Gly-Asp sequence within FN is involved in the cell attachment function of this glycoprotein. It has been hypothesized that platelets have a receptor capable of recognizing the Arg-Gly-Asp sequence in several adhesive proteins and that this platelet receptor is the membrane glycoprotein GPIIb/IIIa.[10] This amino acid sequence has also been found in other proteins that interact with platelets such as fibrinogen, von Willebrand factor, and vitronectin.[11] On the other hand, it has been reported that platelets from thrombasthenic patients lacking the GPIIb/IIIa complex, do not form thrombi in the Baumgartner perfusion system, using both citrated[12] and nonanticoagulated blood.[13]

In this study, we investigated the role of FN in platelet adhesion and in platelet thrombus formation. We used two perfusion models: the annular chamber with rabbit abdominal aorta segments and the flat chamber with coverslips coated with fibrillar purified human collagen type III. Morphometry was used to measure the extent and the state of interacting platelets, as well as to determine platelet thrombus dimensions.

MATERIALS AND METHODS

Collagens

Collagen type III from human umbilical arteries was isolated and purified by the Chandrajajan method.[14] Collagen fibers were prepared as previously described.[15] Briefly, native type fibers were prepared by dissolving the collagen (1 mg/mL) in 50 mmol/L acetic acid and dialized against 20 mmol/L Na_2HPO_4 at 4°C for 48 hours. The collagen fibrils were collected by centrifugation (30 minutes, 30,000 g, 4°C) and resuspended in 20 mmol/L Na_2HPO_4. The collagen concentration in the fibrillar suspension was determined by the hydroxyproline assay.

Fibronectin Depleted Plasma and Fibronectin

FN was isolated from plasma by affinity chromatography as described.[16] FN-depleted plasma contained no detectable FN on electro-immunoassay. The level of FVIIIR:Ag was unchanged and the level of FVIII:RCo ranged from 0.7 to 0.85 U/mL. There was essentially no change in the multimeric structure of von Willebrand factor after passage over the gelatin column. Purity of the isolated FN was assessed by SDS gel electrophoresis according to Laemmli.[17]

Preparation of Perfusates

Blood from normal healthy donors who had taken no drugs ten days before blood collection was anticoagulated with 1:10 vol 110 mmol/L trisodium citrate. Platelet rich-plasma was prepared by centrifugation (ten minutes, 150 g, 20°C). Platelets were washed twice by centrifugation (ten minutes, 500 g, 20°C) in Krebs-Ringer buffer pH 6.0. RBCs were washed three times by centrifugation (ten minutes, 300 g, 20°C) in isotonic saline containing 5 mmol/L glucose. Perfusates were prepared as previously described[15] and consisted of washed platelets (WP), washed RBCs (WRBC) and normal plasma or FN-depleted plasma. Before each perfusion run, the perfusate (15 mL) was reconstituted by adding WRBC to the resuspended platelets (hematocrit 0.4, platelet count 1.9×10^{11} pl/L, final concentration). In some experiments, FN was added to

*$P < .01$.

FN-depleted plasma to obtain a final concentration of 300 μg/mL. The perfusates were incubated for five minutes in a water bath at 37°C before starting the perfusion.

Preparation of the Vessels

Rabbit abdominal aorta segments were obtained from New Zealand rabbits that weighed 2.5 to 2.8 kg. Arteries were excised above the iliac artery and were everted to expose the luminal surface. The endothelium was removed by treatment with α-chymotrypsin as previously described.[18] The everted, de-endothelialized segments, ~14 mm in length, were stored at −80°C until used. Before perfusion, vessel segments were rinsed with 0.02 mol/L phosphate buffered saline (PBS) pH 7.4.

In some experiments, α-chymotrypsin-digested rabbit segments were incubated with purified FN at a concentration of 1 mg/mL for 30 minutes at 20°C. The preincubated vessel segments were thoroughly rinsed with PBS pH 7.4 before being used in perfusions.

Preparation of the Coverslips

Fibrillar collagen (1 mg/mL) was sprayed onto plastic coverslips (Thermanox, Miles Laboratories, Naperville, IL) at a concentration of 20 μg/cm² with a retouching airbrush, as previously described.[15]

Perfusion Experiments

Perfusions were carried out in annular chambers according to Baumgartner,[19] and in flat chambers as described by Sakariassen et al.[20] The annular chambers were used for the arteries and the flat chambers were used for collagen-coated coverslips.

Processing of Vessel Segments and Plastic Coverslips for Cross-Sectional Morphometric Evaluation

Vessel segments. After perfusion, the segments were rinsed with PBS and fixed with glutaraldehyde. The fixed segments were sliced from the supporting rod, dehydrated through a graded series of ethanol concentrations, embedded in JB-4 embedding media (KIT composed of components A, B, and C Polysciences, Warrington, PA), thin-sectioned for light microscopy, and stained with toluidine blue as described.[21]

Collagen-coated coverslips. In perfusions carried out with the flat chambers, the system was rinsed with PBS pH 7.4. following the experiments. The perfused coverslips were carefully removed from the chamber knobs, rinsed thoroughly with 0.02 mol/L PBS pH 7.4 and fixed for one hour in 0.5% glutaraldehyde in 0.1 mmol/L PBS pH 7.4. After one hour of fixation, coverslips were washed in fresh PBS and dehydrated in a graded series of ethanols (30%, 50%, 70%, 96%). Infiltration of the samples was performed in catalyzed JB-4 solution for two hours at 4°C. Embedding of the coverslips was performed in flat molds. The nonperfused side of the coverslips was laid on the bottom of the mold filled with catalyzed JB-4 solution. Polymerization was carried out at 4°C in special containers from which air had been removed by nitrogen current. After complete polymerization, plastic coverslips were carefully peeled off from the JB-4 polymer, leaving the perfused side of the coverslip firmly embedded in the JB-4 polymer. Three-millimeter wide strips of the JB-4 flat blocks were appropriately oriented and vertically embedded in BEEM capsules as described above. Final blocks were vertically sectioned with glass knives. Sections were removed from the cutting edge, floated on water, mounted on glass slides, dried, and stained with 1% methylene blue.

Morphometric Evaluation

Platelet interaction with subendothelium was evaluated according to the basic criteria described by Baumgartner[19] with minor modifications.[21] Basically, platelets or groups of platelets were classified as follows: contact (C), platelets that are attached but not spread on the subendothelium; spread (S), platelets that have spread on the subendothelial surface; aggregate (Ag), aggregates of <5 μm in height; thrombus (T), platelet aggregates of ≥5 μm in height. Total covered surface was obtained by adding C + S + Ag + T. Morphometric evaluation was performed using a manual optical picture analysis system (MOP 20 Kontron) connected to a computer with an automated recognition program, as previously described.[21]

In addition to the morphometric evaluation, we simultaneously determined the cross-sectional areas of all platelet aggregates of >5 μm in height (Thrombus). The sum of all thrombus surface area expressed in square micrometers was related to the perimeter of either rabbit vessel or collagen coated coverslips, in each case 3,400 μm. The result obtained corresponded stereologically to the thrombus volume per unit of surface area of the subendothelium (μm³/μm²), as described elsewhere.[22]

RESULTS

Studies on Platelet Deposition on Rabbit Subendothelium

To assess the role of plasma FN in the interaction of platelets with subendothelium of different thrombogenic properties, we carried out perfusions with vessel segments that had been de-endothelialized by overnight digestion with α-chymotrypsin. Perfusions were performed at two different shear rates, 300 and 1,300 s^{-1}, respectively. Table 1 summarizes the results obtained in the perfusions at a shear rate of 300 s^{-1}. In this group of experiments, plasma FN depletion significantly reduced the percentage of platelet thrombi from 3.5% ± 0.5% to 1.5% ± 0.3% ($P < .01$) and the total coverage surface 17.6% ± 0.5% to 9.8% ± 0.4% ($P < .01$). The percentage of the surface covered by contact and spread platelets, and the platelet aggregates of <5 μm in height were also reduced, although these values were not significant.

Perfusions carried out with α-chymotrypsin–digested rabbit vessels at a high shear rate (1,300 s^{-1}) indicated the role of plasma FN in platelet thrombus formation (Table 2). In these experiments, the surface coverage with platelet thrombi decreased from 14.4% ± 1.0% to 1.6% ± 0.1% ($P < .01$). The total surface coverage was also significantly diminished from 29.2% ± 3.7% to 14.7% ± 3.0% ($P < .01$). No significant differences were observed for the values of contact and spread platelets. Surface coverage with aggregates of <5 μm in height was slightly decreased but of no statistical significance. Figure 1 illustrates the differences by showing micrographs of the vessel wall subendothelium after perfusions at a shear rate of 1,300 s^{-1} with perfusates prepared with normal plasma (Fig 1A) or FN-depleted plasma (Fig 1B).

In both groups of experiments, at low and high shear rates, addition of 300 μg/mL of FN to FN-depleted perfusates restored the values of platelet deposition to those measured in control perfusions.

Treatment of the rabbit vessel with α-chymotrypsin for 18 hours digests all noncollagenous subendothelial proteins, including FN. Attempts to restore vessel FN were made by preincubating the digested vessels with purified human FN. Preincubation of enzymatically-treated rabbit vessel segments with purified human FN (1 mg/mL) for 30 minutes at 22°C did not modify the pattern of platelet adhesion. These results are summarized in Table 3. No significant changes were observed after preincubation of the vascular material with purified FN. For these experiments, FN-depleted plasma was used in the perfusate.

Platelet Deposition on Nonfibrillar and Fibrillar Purified Collagen Type III

To study the role of plasma FN on platelet adhesion to human purified collagen type III, perfusions using the flat chamber perfusion system were performed.[20]

Results are summarized in Table 4. At a shear rate of 300 s^{-1}, the vessel surface covered with platelet aggregates of <5 μm, with platelet thrombi, and the total coverage surface, were reduced from 14.2% ± 1.7% to 8.3% ± 0.8%, from 6.1% ± 1.7% to 2.0% ± 0.7%, and from 31.0% ± 5.0% to 14.8% ± 3.7%, respectively in perfusions carried out with FN-depleted plasma. All these values reached significant levels ($P < .01$).

The values obtained in perfusions performed at a shear rate of 1,300 s^{-1} also indicated the role of plasma FN in the interaction of platelets with purified fibrillar collagen type III. The most significant reduction observed in perfusates prepared with FN-depleted plasma was in the percentage of platelet thrombi, with a decrease from 14.3% ± 3.0% to 3.6% ± 1.0% ($P < .05$). The values of platelet aggregates and of the total coverage surface were also decreased, but were of no significance.

Measure of Platelet Thrombus Volume

The dimensions of the thrombi formed in perfusions carried out at high shear rate with normal, FN-depleted plasma, and FN-depleted plasma to which FN had been added, were performed using the computerized system for morphometric evaluation. The results are shown in Fig 2. In perfusions performed with the annular chamber at a shear rate of 1,300 s^{-1}, the mean thrombus volume per surface area was 0.58 ± 0.11 $\mu m^3/\mu m^2$ for normal perfusates, and 0.12 ± 0.08 $\mu m^3/\mu m^2$ for FN-depleted perfusates, respectively.

Table 3. Platelet Deposition on α-Chymotrypsin–Treated Rabbit Vessels Preincubated With Purified FN

α-Chymotrypsin–digested rabbit vessels were preincubated with purified FN isolated from plasma by affinity chromatography and exposed to blood for ten minutes. Perfusates were prepared with FN-depleted plasma. Values represent mean ± SEM with the number of experiments in parentheses.

Table 4. Platelet Deposition on Fibrillar Collagen Type III

Perfusate	Shear Rate (s^{-1})	Surface Covered (%)				
		Contact	Spread	Ag < 5μm	Thrombus	Surface Coverage
Normal plasma (n = 4)	300	0.6 ± 0.2	10.1 ± 2.1	14.2 ± 1.7	6.1 ± 1.7	31.0 ± 5.0
FN-depleted plasma (n = 3)	300	0.4 ± 0.2	4.2 ± 2.5	8.3 ± 0.8*	2.0 ± 0.7*	14.8 ± 3.7*
Normal plasma (n = 3)	1,300	0.2 ± 0.05	8.1 ± 2.1	36.9 ± 5.3	14.3 ± 3.0	59.5 ± 10.4
FN-depleted plasma (n = 3)	1,300	0.6 ± 0.01	9.0 ± 1.8	29.8 ± 3.5	3.6 ± 1.0*	43.0 ± 6.7

Fibrillar collagen type III was exposed to blood for ten minutes. Values represent mean ± SEM with the number of experiments in parentheses.
*$P < .01$.

These values reached the significant level ($P < .01$). Addition of purified FN to FN-depleted perfusates restored the value of thrombus volume to 0.48 ± 0.12 $\mu m^3/\mu m^2$.

Measure of thrombus volume in perfusions carried out with the flat chamber, using human fibrillar collagen as the substrate for platelet adhesion, displayed similar results. In this set of experiments, a statistically significant decrease ($P < .01$) in the mean thrombus volume per surface area was 0.67 ± 0.09 $\mu m^3/\mu m^2$ in normal perfusions and 0.20 ± 0.10 $\mu m^3/\mu m^2$ in FN-depleted perfusions was observed. The results obtained following the addition of 300 μg/mL of purified FN to FN-depleted perfusates showed a value of 0.60 ± 0.15 $\mu m^3/\mu m^2$, which was similar to the value measured in control perfusions. These results, using both perfusion systems, indicate the importance of plasma FN in platelet thrombus formation.

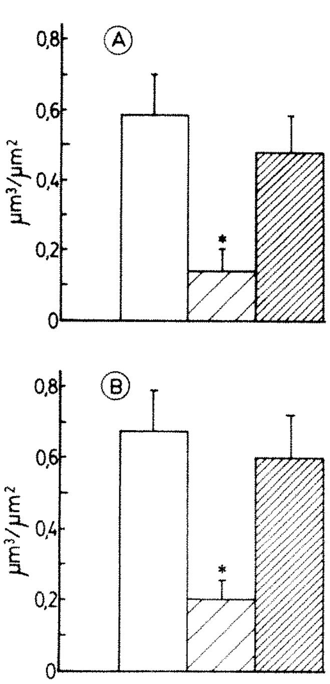

Fig 2. Effects of plasma FN on platelet thrombus formation Platelet thrombus volume per surface area was measured in ten minute perfusions at 1,300 s^{-1} and expressed in $\mu m^3/\mu m^2$. (A) Perfusions were performed with the annular chamber using α-chymotrypsin–digested rabbit segments. The number of experiments were n = 7, n = 6, and n = 3 for normal plasma, FN-depleted plasma, and FN-depleted plasma + FN, respectively. (B) Perfusions were performed with the flat chamber using fibrillar human collagen type III. The number of experiments were n = 4, n = 3, and n = 4 for normal plasma, FN-depleted plasma, and FN-depleted plasma + FN, respectively. □, Normal plasma; ▨, FN-depleted plasma; ▨, FN-depleted plasma + FN. Bars indicate mean thrombus volume per surface area and lines indicate SEM. $P < .01$.

DISCUSSION

It is well documented that FN plays a role in some adhesion-mediated cell functions, including the interaction of platelets with vessel subendothelium.[15,23] In the present study, we investigated the role of plasma FN in platelet adhesion and platelet thrombus formation under flow conditions. To expose flowing blood to collagenous subendothelial and purified human collagen type III surfaces two perfusion systems were used. Platelet-subendothelium interaction was studied using annular chambers, with α-chymotrypsin–digested rabbit arteries, and flat chambers, with coverslips coated with fibrillar human collagen type III. Our results indicated that plasma FN is required for platelet aggregate and platelet thrombus formation, following adhesion in both types of surfaces studied.

The experiments carried out with α-chymotrypsin–treated rabbit vessels, particularly those performed at high shear rate, in which the percentage of thrombus formed is higher, indicate that plasma FN plays an important role in thrombus formation. The fact that average thrombus volume was significantly reduced in FN-depleted perfusions and that the addition of purified FN to the perfusates restored the values to those measured in control perfusions, strongly supports that plasma FN is not only important for the adhesion of platelets to subendothelium, but also for subsequent platelet thrombus growth under flow conditions.

Our results do not agree with those of Houdijk and Sixma,[23] who reported that FN in human artery subendothelium, but not in plasma, was important for platelet adhesion. However, more recently the same investigators found that platelet adhesion to endothelial cell matrix presented a shear-rate dependent requirement for plasma FN.[4] These differences in the relative role of plasma FN on platelet adhesion can probably be explained by differences between the surfaces used for platelet adhesion studies. In our studies, we used α-chymotrypsin–digested rabbit vessels that, as assessed by immunofluorescence staining (unpublished observation), were found to lack intact subendothelial FN, following enzymatic treatment. Preincubation of digested vessels with purified human FN did not enhance platelet deposition on subendothelium at any shear rate studied. This lack of effect may be due to human FN not incorporating into the collagen network of the digested rabbit vessels. This may be caused by differences between animal species or by steric hindrance due to remaining FN fragments.

The experiments performed with the flat chamber using fibrillar collagen type III as a substrate for platelet adhesion displayed similar results to those obtained with enzymatically digested vessel subendothelium. In this system, plasma FN was also found to be required for platelet adhesion and platelet thrombus formation on collagen coated surfaces, at both low and high shear rates. The observation that in both experimental systems used, addition of purified FN to the perfusates restored the values obtained for control perfusions indicating that the effects on platelet deposition were due to depletion of plasma FN.

Until now other plasma proteins such as fibrinogen[24] and von Willebrand factor[25] have been suggested to play a role in platelet-platelet interaction. There is evidence that fibrinogen, von Willebrand factor, and FN bind to the GPIIb/IIIa membrane complex of activated platelets. Recently, various investigators explored the role of GPIIb/IIIa in platelet adhesion to subendothelium, using the Baumgartner perfusion system. Sakariassen et al[12] showed a defect in platelet adhesion at high shear rates after blocking the GPIIb/IIIa complex with specific monoclonal antibodies. Furthermore, Weiss et al[13] reported that platelets deficient in GPIIb/IIIa do not spread normally on the subendothelial surface. However, the specific binding site of FN to the GPIIb/IIIa receptor and its implications in platelet function are still not well understood. Thus, it has been reported that FN binds to specific divalent cation-dependent receptors on washed, thrombin stimulated platelets,[26] but does not bind to ADP- or epinephrine-stimulated platelets, whereas, fibrinogen and von Willebrand factor do.[27] These observations suggest separate binding sites for FN in the platelet membrane. Moreover, Dixit et al[28] described a monoclonal antibody directed against FN that does not interfere with the function of the cell binding domain of the FN. The ability of this antibody to inhibit platelet aggregation suggests that there is a functional site present in FN that has a direct role on platelet aggregation. Furthermore, the results reported by Parise and Phillips[29] demonstrate that FN can bind directly to purified GPIIb/IIIa complex, strongly suggesting that it has the potential to function as a platelet receptor for FN.

Our results indicated that under flow conditions plasma FN, in addition to supporting platelet adhesion to collagenous subendothelial surfaces and to purified collagen type III, influences platelet thrombus formation. It is feasible that binding of FN to GPIIb/IIIa, or to another putative receptor present in activated platelets, favors interaction between platelets and contributes to the development of platelet thrombi. In conclusion, the results we present here indicate that plasma FN is one of the adhesive proteins required for platelet thrombus growth under flow conditions.

Membrane-Associated Sickle Hemoglobin: A Major Determinant of Sickle Erythrocyte Rigidity

By Evan A. Evans and Narla Mohandas

Micropipette aspiration tests on single erythrocytes have previously shown that the static rigidity (membrane shear modulus) of oxygenated sickle cells increased with increasing hemoglobin concentration, whereas the rigidity of normal cells was independent of hemoglobin concentration. Moreover, it was observed that after mechanical extension, sickle cells exhibited persistent deformation more frequently and to a greater extent than normal cells. To ascertain if differences in association of normal and sickle hemoglobin with the membrane could account for these observations, we measured rheologic properties of normal membranes reconstituted with sickle hemoglobin and sickle membranes reconstituted with normal hemoglobin. The static rigidity of normal ghosts reloaded with sickle hemoglobin was higher than those of either normal ghosts reloaded with normal hemoglobin or native normal cells. On the other hand, the increased rigidity of native sickle cells decreased to near-normal values following reconstitution with normal hemoglobin. Furthermore, we observed that normal ghosts reconstituted with sickle hemoglobin exhibited persistent bumps after mechanical extension, but no bumps formed on normal ghosts reconstituted with normal hemoglobin. Moreover residual bumps were not produced on sickle cells reloaded with normal hemoglobin. Since mechanical characteristics peculiar to sickle cells could be induced in normal cells by incorporation of sickle hemoglobin, *and* since normal characteristics could be restored to sickle cells by incorporation of normal hemoglobin, we suggest that the interaction of sickle hemoglobin with the cell membrane is responsible for augmented static rigidity of oxygenated sickle erythrocytes.

STATIC and dynamic deformabilities of erythrocytes are important determinants of microcirculatory blood flow because they determine the rate of entry of erythrocytes into small capillaries, which in turn influences the pressure drop across the small vessels and the flow distribution within the microcirculation.[1-8] The microrheologic behavior of single erythrocytes is governed by both membrane and cytoplasmic properties. As such it has been difficult to evaluate whether or not sickle cell membrane deformability has been compromised or altered by the disease independent of the effect of sickle hemoglobin polymerization on the cytoplasmic viscosity. To determine whether or not the mechanical properties of the sickle cell membrane are altered, we previously studied static and dynamic deformability properties of normal and sickle erythrocytes in the oxygenated state as a function of cell hemoglobin concentration.[8] These studies showed that the dynamic rigidity was indistinguishable between oxygenated normal and sickle cells when examined as a function of hemoglobin concentration and that the dynamic rigidity was increased markedly with increasing cell hemoglobin concentration. On the other hand, the static rigidity of sickle cells was clearly greater than that of normal cells. Static rigidity of sickle erythrocytes increased with increasing hemoglobin concentration, reaching abnormally high values at cell hemoglobin concentrations above 46 g/dL, while static rigidity of normal erythrocytes was independent of hemoglobin concentration. A striking observation made during these studies was that sickle cells exhibited persistent or plastic deformation more frequently and to a greater extent than normal cells following the static membrane extension test. This type of material behavior indicated that there is probably a thin hemoglobin gel layer adsorbed to the cytoplasmic face of the membrane and that this layer is more developed in sickle cells than normal cells at equivalent cell hemoglobin concentrations.

To further illuminate the influence of membrane-associated hemoglobin on erythrocyte rheology, the following experimental approach was undertaken: sickle and normal erythrocytes were ghosted and reloaded with the opposite type of hemoglobin solution, and the membrane extensional properties were measured. We find that mechanical characteristics peculiar to sickle cells could be induced in normal cells by incorporation of sickle hemoglobin *and* that normal characteristics could be restored to sickle cells by incorporation of normal hemoglobin, suggesting that interaction of sickle hemoglobin with the cell membrane may be an important determinant of the augmented extensional rigidity of oxygenated sickle cells and plastic-like behavior of the membrane.

METHODS

Cell preparation. Blood was drawn from five patients with homozygous sickle cell disease and two normal volunteer donors into acid citrate dextrose. To isolate cell populations whose densities (and therefore intracellular hemoglobin concentrations) were narrowly defined, erythrocytes were separated by using discontinuous Stractan density gradients (St. Regis Paper Co, Tacoma, WA).[9,10] The density of the Stractan layers ranged from 1.088 to 1.139 g/mL in 0.009-g/mL increments. Erythrocytes trapped between the interfaces of successive layers were removed with a Pasteur pipette, with care to avoid contamination with erythrocytes from the less dense regions of the gradient. The isolated erythrocytes were washed three times with phosphate-buffered saline (PBS: 10 mmoL/L phosphate,

pH 7.4, 290 mosm/kg) and resuspended in PBS at a hematocrit of 5%. Cell hemoglobin concentration of isolated erythrocyte populations was determined from spectrophotometric measurements of hemoglobin as the cyanomethemoglobin complex and from spun hematocrit.

Hemoglobin solutions for use in reconstitution experiments were prepared by lysing at 0°C 1 vol of well-oxygenated normal or sickle cells washed in pH 6.0 phosphate buffer with 9 vol of deionized water. The pH of the lysed cell suspension was adjusted to be between 6.2 and 6.3 to aggregate cell membranes, and the suspension was centrifuged at 18,000 rpm for five minutes in a Sorvall RC-2B centrifuge. The supernatant hemoglobin solution was carefully removed and concentrated using a sterile Amicon ultrafiltration cell with a DPO2 membrane. The concentrated hemoglobin solutions were freshly made for each of the reconstitution experiments.

Cytoplasmic reconstitution. To assess the relative contribution of altered membrane organization to rheologic properties of sickle erythrocytes, we prepared hybrid erythrocytes consisting of normal erythrocyte membranes reconstituted with sickle hemoglobin and sickle erythrocyte membranes reconstituted with normal hemoglobin using the exchange hemolysis technique described by Clark and Shohet.[11]

In brief, density-fractionated normal or sickle erythrocytes were washed once with PBS and once with pH 6.0, 290 mosm sodium phosphate solution and placed on ice. One milliliter of washed and packed erythrocytes was lysed with 39 mL of ice-cold lysing buffer (10 mmoL/L sodium phosphate, pH 6.0 with 1 mmoL/L EDTA and 0.3 gm/dL dialyzed bovine serum albumin [BSA]). After two minutes of incubation on ice, the membranes were spun down and the supernatant hemoglobin solution removed. Three milliliters of cold-concentrated–donor-hemoglobin solution, previously prepared, was added to the membranes and incubated on ice for five minutes. Small volumes of concentrated adenosine triphosphate (ATP) and $MgCl_2$ solutions were added to the membrane preparations to obtain final concentrations of 1 mmoL/L Mg^{++} and 250 μm ATP. After a sufficient volume of concentrated KCl solution (6900 mosm) was added to restore the tonicity to 290 mosm, the membrane suspension was incubated at 37°C for one hour to promote membrane resealing. The reconstituted hybrid erythrocytes were spun on Stractan density gradients to obtain cells with hemoglobin concentration greater than 28 g/dL.

To verify that the hemoglobin reconstitution procedure did result in loading individual cells with the requisite hemoglobin concentration, a simple optical density method was developed for use with the video microscope system. Absorption of light (at the 436-nm line of a mercury source) was quantitated directly by measurement of the video voltage levels within the cell image, V_c, at the thick toroidal region or rim of the cell compared differentially with the voltage level, V_i, in the clear field outside the cell (both voltages adjusted for dark field levels).* The fractional absorption, $A = (V_c - V_i)/V_i$, was then normalized by the cell thickness to provide a specific absorption, A/d. The cell thickness was measured by manipulation of the cell into an edge-on orientation for observation. The specific absorption was measured on ten to 20 cells obtained from discrete Stractan density fractions both for native red cells and red cells reloaded with various hemoglobin concentrations. The results are cumulated in Fig 1, which represents a "calibration curve" for conversion of optical density to cell hemoglobin concentration with our videomicroscope system. Statistical variations represent uncertainty in cell thickness measurements (because of diffraction limitations) convolved with density variations among cells trapped within a discrete Stractan density level. Even though this video intensity method is not very accurate, it provides a simple approach for simultaneous evaluation of individual cell hemoglobin concentration along with the mechanical tests. Erythrocyte morphology for this range of optical density levels and hemoglobin concentrations is illustrated by the videomicrographs of cells shown in Fig 2. Discoid sickle cells following reconstitution with normal hemoglobin had discoid morphology. Moreover hybrid erythrocytes produced by reconstitution of irreversibly sickled cells with normal hemoglobin continued to exhibit irreversibly sickled shape.

Analytic and experimental approaches to measurement of rheologic properties. Cells deform by extension and folding limited by fixed surface area and volume. As such the static rigidity properties of erythrocytes are quantitated by membrane extension and bending moduli, μ and B; the dynamic rigidities are proportional to the static rigidities multiplied by the time constants measured for recovery from extension (τ_e) and folding (τ_f) deformations divided by the deformation time (ie, the capillary entrance time).[8] Hence because of the rapid entry into small capillaries, dynamic resistance is most likely the dominant impedance to cell transport through the microcirculation. In addition to these viscoelastic properties of the cell, recoverability of the cell shape after deformation characterizes the resilience of the cell; plastic or persistent shape changes following deformation indicate an altered structural arrangement in the membrane that could lead to aberrant cell morphologies such as the irreversibly sickle cells (ISC).

In this study we have focused on the extensional properties of the membrane to evaluate possible "thickening" of the membrane by membrane-associated hemoglobin and resultant changes in membrane properties. For cells with normal densities, the static extensional rigidity, μ, is essentially an elastic modulus that characterizes reversible membrane deformations, ie, the forces that produce extension and recovery follow the same curves with little or no hysteresis.[8,12] For dense cells, on the other hand (especially sickle cells), the rigidity μ is measured as the stiffness coefficient for "loading" or extension of the membrane because there is significant

*It is important to note that common video cameras have sophisticated automatic amplification circuits. In general, the system adjusts the gain based on the darkest and brightest portions of the image. Hence to employ these cameras as we have, it is necessary to have a portion of the image field dark (eg, provided by a circular aperture just inside video image "box") and to have a constant illumination source (eg, mercury arc lamp). If the illumination is changed or the dark border is absent, then the video signal levels will be internally adjusted.

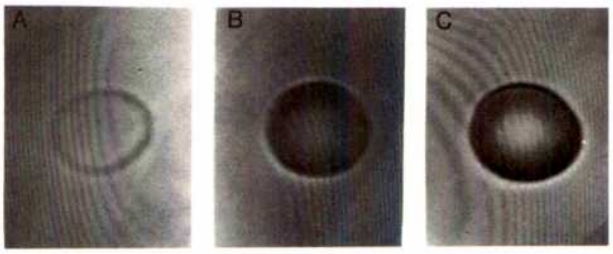

Fig 2. Videomicrographs of reconstituted cells with varying hemoglobin concentrations. The hemoglobin concentration of the cells shown is as follows: (A) 8 g/dL, (B) 30 g/dL, and (C) 34 g/dL.

hysteresis observed as the cell is allowed to recover.[8] After removal of the forces for extension, there is often persistent or residual deformation. These inelastic effects are characteristic of a gel-like material (ie, with a plastic-like yield stress). In the dynamic recovery after cells are released from extensional deformations, the shape recovery process is driven by membrane elasticity but is limited by viscous dissipation in the membrane and in the cytoplasmic and extracellular media. Since the cytoplasmic viscosity is nearly an order of magnitude larger than that of the extracellular medium, the extensional recovery time is approximately given by[13]:

$$\tau_e \sim (\eta_m + \eta_{Hb} \times d/2)/\mu$$

where η_m is the membrane surface viscosity (dyn-s/cm); η_{Hb} is the cytoplasmic viscosity (dyn-s/cm^2); d is the characteristic thickness of the cell. For hemoglobin concentrations from 33 to 40 g/dL, the viscosity ranges from 0.06 to 0.3 dyn-sec/cm^2.[14] Based on a cell thickness dimension of about 2×10^{-4} cm and the membrane elastic modulus measured for normal cells of 6×10^{-3} dyn/cm, we would expect that cells should recover their initial shapes after extension in about 10^{-3} to 10^{-2} seconds for this range of hemoglobin concentrations if there were no membrane dissipation. However, the observed recovery times are 10^{-1} seconds or greater, which indicates that membrane viscous dissipation is dominant and that cytoplasmic viscosity can be neglected. During this study we have tested this conclusion with the use of a cytoplasmic reconstitution method (and by attempting to alter the extent of hemoglobin association with the membrane at constant bulk cytoplasmic hemoglobin concentration). Here it is emphasized that "membrane" includes all intrinsic molecular structures (eg, the amphiphilic molecular double layer or plasmalemma) plus extrinsic or associated structures (eg, the spectrin network or membrane skeleton *and* associated or trapped hemoglobin).

Details of the micromechanical system and tests used to measure erythrocyte mechanical properties have been previously described.[8] Briefly, the membrane extensional rigidity was derived from observation of the cell length aspirated into a small micropipette in proportion to the increase in suction pressure P. Analysis of this experiment has shown that μ is proportional to the derivative of the pressure with respect to length:

$$\mu \propto R_p^2 \times dP/dL$$

where R_p is the pipette inner radius.

The dynamic time constant for recovery τ_e following extensional deformations was derived from tests where erythrocytes were extended end to end by diametrically opposed pipettes. The cells were quickly released and the ratio of length to width was measured as a function of time. The time constant for recovery was derived from correlation of the analytic model for viscoelastic behavior of the red cell membrane with the observed length-to-width recovery.[8,13]

Table 1. Static Extensional Rigidity of Intact Normal and Sickle Erythrocytes as a Function of Cell Hemoglobin Concentration

Erythrocytes	Shear Modulus ($\times 10^{-3}$ dyn/cm)
Normal	
32 g/dL	7.8 ± 0.85
42 g/dL	8.6 ± 1.5
Sickle	
32 g/dL	9.2 ± 2.6
43.3 g/dL	16.5 ± 2.7
44.4 g/dL	21.0 ± 7.8

Values are mean ± SD.

Rheologic properties of 20 intact cells from each density fraction and at least 20 variously reconstituted cells were measured.

RESULTS

Membrane extensional rigidity of native and hybrid erythrocytes. The measured values for static extensional rigidity (μ) of density-fractionated intact normal and sickle erythrocytes are shown in Table 1 for narrowly defined ranges of cell hemoglobin concentration. The shear modulus of normal erythrocytes was independent of cell hemoglobin concentration, while that of oxygenated sickle erythrocytes increased with increasing cell hemoglobin concentration. The shear modulus of sickle erythrocytes with hemoglobin concentration of 44.4 g/dL was 2.5-fold higher than that of either normal erythrocytes or sickle erythrocytes with a hemoglobin concentration of 32 g/dL.

The shear modulus values for variously reconstituted hybrid erythrocytes is shown in Table 2. The elastic shear modulus of normal membranes reconstituted with normal hemoglobin was the same as that of intact normal erythrocytes. In contrast, normal erythrocytes reconstituted with sickle hemoglobin exhibited higher values of extensional rigidity compared to normal membranes reconstituted with normal hemoglobin ($13.1 \; v \; 8.6 \times 10^3$ dyn/cm). The magnitude of the shear modulus value appeared to depend on the hemoglobin concentration of the reconstituted cells. The higher the hemoglobin concentration (as judged by video intensity measurements), the larger the shear modulus of normal erythrocytes reconstituted with sickle hemoglobin. The shear modulus of sickle membranes derived from either low- or high-density sickle cells and reconstituted with normal hemoglobin was very similar to that of normal erythrocytes. The reconstitution of membranes from sickle erythrocytes with a hemoglobin concentration of 44.4 g/dL with normal hemoglobin resulted in the decrease of shear

Table 2. Static Extensional Rigidity of Reconstituted Normal and Sickle Erythrocytes

	Shear Modulus ($\times 10^{-3}$ dyn/cm)
Normal membranes + normal hemoglobin	8.7 ± 1.3
Normal membranes + sickle hemoglobin	13.1 ± 2.9
Sickle membranes from high-density cells (44.4 g/dL) + normal hemoglobin	10.1 ± 2.3

Values are mean ± SD.

modulus value from 21.0 to 10.1 × 10^{-3} dyn/cm. The reconstitution procedure used during these studies was considered successful, since cell morphologies appeared unchanged; also, both optical density and edge-on observation of cells indicated a large hemoglobin uptake; and normal cells reloaded with sickle hemoglobin sickled upon deoxygenation, while sickle cells reloaded with normal hemoglobin did not.

Reversibility of membrane deformation. During the micromechanical measurement of membrane extensional rigidity, we also observed that the curves for aspirated length *v* suction pressure (which are used to derive the value for shear modulus) exhibited different patterns for variously reconstituted cells (Figs 3 and 4). For normal membranes reconstituted with normal hemoglobin, the relationship between aspirated length *v* suction pressure was the same during increasing aspiration pressure (loading phase) and during decreasing aspiration pressure (unloading phase, Fig 3 A). The identical relationship observed between the two variables during both phases of loading and unloading indicates the true elastic behavior of this membrane. In contrast, for normal membranes reconstituted with sickle hemoglobin, the curve of aspirated length *v* suction pressure was markedly different during loading and unloading phases (Fig 3 B). The detection of hysteresis associated with the loading and unloading phases indicates that the normal membrane reconstituted with sickle hemoglobin underwent plastic-like behavior. Similar material behavior was previously seen by us for all sickle erythrocytes irrespective of cell hemoglobin concentration.[8] When reconstituted sickle cells were examined, we found that sickle membranes from the low-density fraction reconstituted with normal hemoglobin exhibited elastic behavior (Fig 4 A), while sickle membranes from the high-density fraction reconstituted with normal hemoglobin exhibited plastic-like behavior (Fig 4 B).

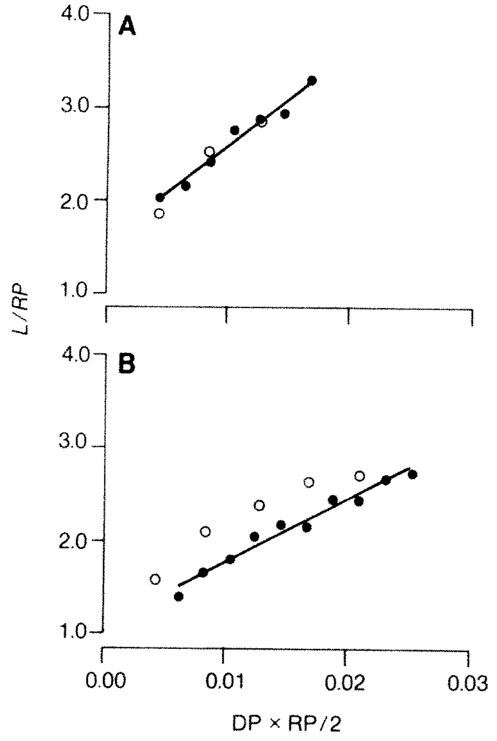

Fig 3. Plot of membrane tension DP × RP/2 (dynes per centimeter, abscissa) *v* the aspiration length normalized by the pipette radius (L/RP) in the micropipette suction experiment. DP is the aspiration pressure; L, the aspirated cell length; and RP, the inner radius of the micropipette. The dark circles are the loading phase of the experiment; the slope of the straight-line fit shown here gives the modulus of extensional rigidity for the cell membrane. The open circles are the unloading phase of the aspiration experiment; the difference between the loading and unloading phases represents the lethargic recovery of the cell membrane after extension for periods of time from two to three minutes. The data shown here are for (A) normal membranes reconstituted with normal hemoglobin; and (B) normal membranes reconstituted with sickle hemoglobin.

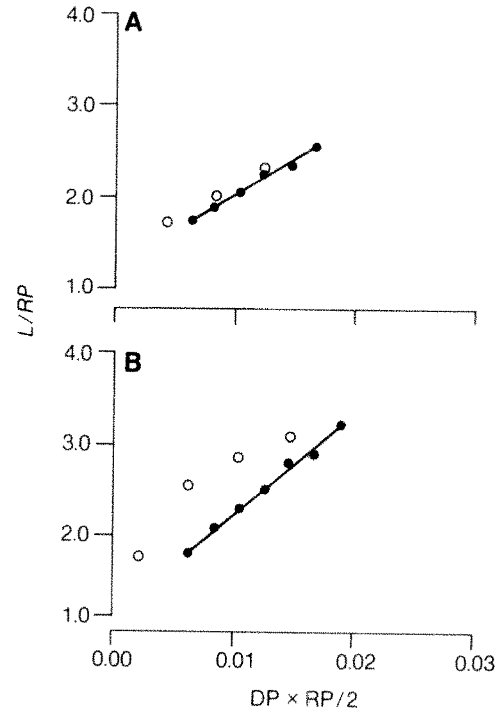

Fig 4. Plot of membrane tension DP × RP/2 (dynes per centimeter, abscissa) *v* the aspiration length normalized by the pipette radius (L/RP) in the micropipette suction experiment. DP is the aspiration pressure; L, the aspirated cell length; and RP, the inner radius of the micropipette. The dark circles are the loading phase of the experiment; the slope of the straight-line fit shown here gives the modulus of extensional rigidity for the cell membrane. The open circles are the unloading phase of the aspiration experiment; the difference between the loading and unloading phases represents the lethargic recovery of the cell membrane after extension for periods of time from two to three minutes. The data shown here are for (A) sickle membranes from the low-density fraction reconstituted with normal hemoglobin; and (B) sickle membranes from the high-density fraction reconstituted with normal hemoglobin.

The plastic-like behavior of the membrane observed during these studies was also reflected by residual, persistent bumps on the membrane surface following the release of the cell from the pipette (Fig 5). To further assess the roles of sickle hemoglobin interaction with the membrane and of alterations in membrane skeletal organization in inducing

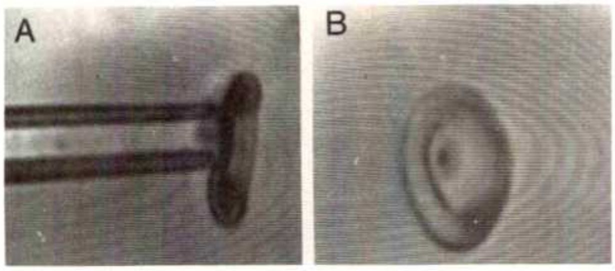

Fig 5. Persistent or residual bumps following mechanical extension. (A) Videomicrograph of pipette aspiration of a normal cell reconstituted with sickle hemoglobin. (B) Videomicrograph of the same cell following its release from the micropipette. The residual, persistent bump on the membrane surface following the release of the cell from the pipette can be clearly seen.

this plastic-like behavior, we determined the fraction of variously reconstituted cells exhibiting persistent bumps following extensional deformation (Table 3). A vast majority (97%) of normal membranes reconstituted with sickle hemoglobin exhibited persistent or residual bumps following extensional deformation, whereas none of the normal membranes reconstituted with normal hemoglobin exhibited such material behavior. Sickle membranes from low-density sickle erythrocytes reconstituted with normal hemoglobin also did not exhibit persistent deformation (3%). Interestingly we found that sickle membranes derived from hyperdense sickle erythrocytes and reconstituted with normal hemoglobin exhibited persistent bumps following extensional deformation (85%).

Dynamic response to extension of native and hybrid erythrocytes. The dynamic response of intact and reconstituted cells to extensional deformation was determined by quantitating the time constant for recovery of the unstressed shape following deformation. To accomplish this, an individual cell was extended end to end by diametrically opposed pipettes such that little buckling or curvature change of the membrane surface took place; then the cell was quickly released and the length-to-width recovery time was analyzed.

Table 3. Residual or Persistent Bumps on Reconstituted Cells Following Extensional Deformation

	No. of Cells Studied	Cells With Residual Bumps	Cells With Residual Bumps (%)
Normal membranes + normal hemoglobin	30	0	0
Normal membranes + sickle hemoglobin	30	29	97
Sickle membranes from low-density cells (32 g/dL) + normal hemoglobin	30	1	3
Sickle membranes from high-density cells (44.4 g/dL) + normal hemoglobin	20	17	85

Table 4. Time Constants for Recovery from Extensional Deformation for Intact and Reconstituted Erythrocytes

	Recovery Time (s)
Sickle erythrocytes	
32 g/dL	0.12 ± 0.03
42 g/dL	0.73 ± 0.19
43.3 g/dL	1.20 ± 0.42
Normal membranes + normal hemoglobin	0.09 ± 0.04
Normal membranes + sickle hemoglobin	0.08 ± 0.02
Sickle membranes from high-density cells (43.3 g/dL) + normal hemoglobin	0.09 ± 0.04

Values are mean ± SD.

The time constant for extensional recovery was derived from the best fit of the viscoelastic model of the observed data.[13] Time constants for recovery from extensional deformation for intact and reconstituted cells are shown in Table 4. The time constant for extensional recovery was strongly dependent on hemoglobin concentration for both normal and sickle erythrocytes, a finding consistent with our previous data.[8] As the cell hemoglobin concentration increased from 32 g/dL to 43.3 g/dL, the recovery times of oxygenated sickle cells increased from 0.12 to 1.2 seconds. The time constant for extensional recovery for variously reconstituted cells was very similar and was slightly less than that measured for low-density normal and sickle cells (0.09 second *v* 0.12 second for intact cells). Normal membranes reconstituted with either normal or sickle hemoglobin and sickle membranes reconstituted with normal hemoglobin all exhibited a time constant for extensional recovery of about 0.09 second. Moreover the time constant for extensional recovery was unaltered when cells were reconstituted with either normal or sickle hemoglobin in the concentration range of 8 to 31 g/dL, although cytoplasmic viscosity is changed by sixfold over this range of hemoglobin concentration.

DISCUSSION

Measurement of rheologic properties of reconstituted normal and sickle erythrocytes has enabled us to identify an important role for sickle hemoglobin interaction with the cell membrane in determining the extensional rigidity and plastic-like behavior of the sickle erythrocyte membrane. Our finding that the shear modulus of normal cells is increased following reconstitution with sickle hemoglobin and that the augmented shear modulus of sickle cells is decreased to normal values following reconstitution with normal hemoglobin implies that sickle hemoglobin interaction with the membrane is a major determinant of increased shear modulus of oxygenated sickle cells. Furthermore the finding that low-density sickle cells no longer exhibit plastic-like behavior following reconstitution with normal hemoglobin and that normal membranes that previously exhibited elastic behavior can be made to undergo plastic deformation following reconstitution with sickle hemoglobin suggests that sickle hemoglobin interaction with the membrane may also be responsible for the plastic-like behavior of intact cells. However, our inability to eliminate the plastic-like behavior of dense sickle cells following reconstitution with normal hemoglobin suggests that either continued association of sickle hemoglobin with the membrane or irreversible alterations in skeletal protein associations may also contribute to the plastic deformation of the subpopulation of sickle cells.

Increased association of sickle hemoglobin with the erythrocyte membrane has previously been documented by a number of investigators.[15-21] Using the spin-label electron paramagnetic resonance technique, Fung et al[18] and Fung and Lilley[21] showed enhanced binding of sickle hemoglobin to membrane at physiologic pH when compared to normal hemoglobin. Eisinger et al,[20] using resonance energy transfer measurements on intact, oxygenated sickle erythrocytes, showed that concentration of sickle hemoglobin proximal to the membrane (h_b) was significantly higher than the bulk hemoglobin concentration in the cytoplasm (h_c) and that the ratio of these two concentrations (h_b/h_c) increased from 1.0 to 1.5 as cell hemoglobin concentration increased from 34 g/dL to 45 g/dL. This increase in sickle hemoglobin concentration near the membrane was not seen in ghosts. In contrast, in normal erythrocytes, hemoglobin concentration proximal to the membrane was less than the bulk hemoglobin concentration ($h_b/h_c = 0.7$); and the ratio of h_b to h_c did not change as the cell hemoglobin concentration increased from 34 to 42 g/dL. These findings of a concentration-dependent increase in the association of sickle hemoglobin but not of normal hemoglobin with the membrane, as well as the reversible nature of the hemoglobin interaction with the membrane, are consistent with our rheologic data. The hemoglobin binding data lend strong support to our suggestion that the augmented extensional rigidity of sickle cells and their increased tendency to undergo plastic-like behavior may be mediated by the increased interaction of sickle hemoglobin with the membrane.

The finding that dense dehydrated sickle cells continue to exhibit plastic-like behavior following reconstitution with normal hemoglobin implies that either strong association of sickle hemoglobin with these membranes or alterations in normal membrane skeletal protein organization may be responsible for this type of material behavior. Biochemical evidence to support both these types of membrane changes has previously been identified in dense dehydrated sickle cells.[22-25] With the present data it is difficult to determine the relative contributions of these two membrane alterations to the observed material behavior of dense sickle cells. It should be noted, however, that following reconstitution with normal hemoglobin the extensional rigidity of this subpopulation of sickle cells showed marked decrease, implying that reversible association of sickle hemoglobin with the membrane is still the dominant cause of the increased static rigidity of dense sickle cells.

The dynamic rigidity of intact normal and sickle cells, quantitated by measuring time constants for extensional recovery, was found to be strongly dependent on cell hemoglobin concentration, data consistent with our prior observations.[8] The finding that the time constant for extensional recovery was unaltered when cells were reconstituted with either normal or sickle hemoglobin in the concentration range of 8 to 31 g/dL while the cytoplasmic viscosity is changed by sixfold over this range of hemoglobin concentration lends support to earlier theoretical calculations that membrane viscosity and not cytoplasmic viscosity is the key determinant of energy dissipation during recovery from extensional deformation.[4,13,26] The marginal decrease in extensional recovery times for reconstituted cells compared to intact cells (0.09 second *v* 0.12 second) suggests loss of some membrane-bound material during the lysing and reloading procedure. Similar decreases in recovery times for ghost membranes have previously been seen by other investigators.[27]

From our current studies it is clear that rheologic properties of oxygenated sickle cells are strongly influenced by hemoglobin interaction with the cell membrane. The augmented extensional rigidity of sickle cells and their increased tendency to undergo plastic deformation appears to be the result of increased concentration of sickle hemoglobin adjacent to the membrane. The data we have obtained also provide some new insights into the biophysical consequences of the previously described interaction between sickle hemoglobin and cell membrane.

ACKNOWLEDGMENT

We would like to thank Dr William Lande, Dr Stephen Embury, and Klara Kleman for providing us with sickle blood samples. We would also like to acknowledge the expert assistance of James Harris in the preparation of this manuscript, and the expert technical assistance of Andrew Leung in performing the micropipette experiments.

c-fos Oncogene Expression in Human Hematopoietic Malignancies Is Restricted to Acute Leukemias With Monocytic Phenotype and to Subsets of B Cell Leukemias

By Antonio Pinto, Giulia Colletta, Luigi Del Vecchio, Rita Rosati, Vincenza Attadia,
Renato Cimino, and Alfonso Colombatti

To evaluate relationships between *c-fos* proto-oncogene expression and specific lineages of hematopoietic differentiation we analyzed the constitutive and TPA-induced expression of the *c-fos* gene in a wide variety of fresh human leukemic cells.

High constitutive *c-fos* expression was detected in acute leukemias with monocytic phenotype (FAB M4/M5) and in subsets of B lymphoid leukemias, some of which coexpressed B lymphocytic and monocytic markers. Conversely, low basal levels of *c-fos* transcripts were found in pure acute granulocytic leukemias (FAB M1/M2/M3), in erythroleukemias (FAB M6), in the great majority of B, and in all T lymphoid leukemias. TPA-induced *c-fos* expression seems to correlate with monocytoid differentiation only when sustained levels of transcripts (ie, detectable for at least 24 hours) were detected. Sustained *c-fos* expression was in fact observed only in those myeloid or lymphoid cells that acquired a stable monocyte-like phenotype in response to the phorbol ester. These results indicate that high constitutive *c-fos* expression may identify myelomonocytic-oriented forms of leukemia, specific subsets of B lymphoid malignancies, and at least some cells terminally differentiated in vitro to a monocyte-like phenotype. *c-fos* oncogene expression can therefore be regarded as an additional marker for the subclassification of human leukemias.

CHANGES in oncogene expression have been described in hematopoietic cells as linked to cell growth or differentiation.[1-3] In vitro induction of differentiation of murine and human leukemic cells by agents such as dimethylsulfoxide (DMSO),[4-6] retinoic acid (RA),[4] tetradecanoil phorbol acetate (TPA),[6,7] 1,25-$(OH)_2$ D_3,[8] hexamethylenebisacetamide (HMBA),[9] or physiologic regulators like colony-stimulating factor (CSF),[10,11] is in fact associated with a decreased expression of the previously overexpressed oncogenes *c-myc* and *c-myb*. These changes have been related to the observed inhibition of cell proliferation rather than to the induction of differentiation toward a specific lineage. Only recently a number of reports have appeared that link the expression of cellular oncogenes to a specific pathway of hematopoietic differentiation. Increasing amounts of two cellular oncogene transcripts, *c-fos* and *c-fms*, accumulate in hematopoietic cells as the monocytic maturation proceeds.[12-14] Induction of differentiation of murine myelomonocytic cells WEHI-3 into macrophages by CSF and actinomycin D is accompanied by a remarkable increase in *c-fos* transcripts, maximal three days after induction.[10] Furthermore a rapid induction of the *c-fos* oncogene has been reported during TPA-induced monocytic differentiation in human cell lines HL-60[12,14] and U-937.[15] In this case the kinetics of induction was quite different, since *c-fos* transcripts reach their maximal levels 30′ to 40′ following TPA exposure and decrease rapidly thereafter to levels significantly superior to those of uninduced cells. Accordingly, high levels of *c-fos* RNA transcripts have been detected in primary cultures of mouse peritoneal macrophages.[12] On the other hand, no increase in *c-fos* transcripts was observed when HL-60 cells were induced to differentiate into granulocytes by DMSO.[15] These observations suggest that *c-fos* expression is associated with differentiation along the monocyte/macrophage pathway and that the *fos* oncogene may play a role in different events occurring during monocytic maturation.[15,16]

Most of these studies have been conducted on established leukemic cell lines, adapted to grow in vitro for a long time, whose behavior may not necessarily reflect all events occurring in leukemic cells in vivo. Conversely, the analysis of fresh cell samples from a wide variety of leukemias, a disease regarded as a clonal expansion of cells reflecting the phenotypes of normal hematopoietic cells at various stages of maturation,[17,18] may represent a more useful approach by which to investigate the lineage-specific expression of the fos oncogene and may provide some hints on the pathophysiology of hematologic malignancies. Our results show that constitutive *c-fos* expression in human hematopoietic tumors is restricted to myeloid cells displaying markers of monocytic differentiation and to subsets of B cell malignancies, some of which coexpress lymphocytic and monocytic markers.

MATERIALS AND METHODS

Isolation of leukemic cells. Fresh leukemic cells were obtained from the peripheral blood or bone marrow of patients diagnosed as having acute nonlymphoid leukemia (ANNL), acute lymphoid

leukemia (ALL), chronic lymphocytic leukemia (CLL), prolymphocytic leukemia (PLL), and hairy cell leukemia (HCL). All samples were collected before chemotherapy and after informed consent. Diagnoses were based on cell morphology plus standard cytochemical stainings, and acute leukemias were classified according to the French-American-British (FAB) criteria[19] in acute myeloid/granulocytic leukemia (AML; FAB M1, M2, M3), acute myelomonocytic leukemia (AMML; FAB M4), acute monocytic leukemia (AMoL; FAB M5), and acute erythroleukemia (AEL; FAB M6). Only patients who had at least 80% of leukemic cells in peripheral blood or bone marrow were chosen as donors.

Mononuclear cells were purified on a Ficoll-Hypaque (FH) gradient and subjected to two cycles of adherence on a plastic culture dish for one hour at 37°C. Such procedure yielded a population of leukemic cells more than 90% pure and virtually free of contaminating normal monocytes as revealed by May-Grünwald-Giemsa (MGG) and cytochemical stainings of cytospin preparations. Leukemic cells were processed for RNA extraction soon after Ficoll purification to evaluate constitutive *c-fos* expression or were cultured in the presence of TPA as described below.

Culture conditions and in vitro differentiation. Fresh leukemic cells were seeded at a concentration of 1×10^6/mL in tissue culture dishes (Falcon) in RPMI 1640 medium supplemented with 10% heat-inactivated fetal calf serum (FCS, Flow Laboratories Inc, Irvine Ayrshine, UK) and 4 mmol/L glutamine. TPA (Sigma Chemical Co, St. Louis) dissolved in DMSO was added to a final concentration of 20 ng/mL. Control cultures were grown in 0.002% DMSO. After 30' or 24 hours of incubation at 37°C in a humidified atmosphere of 5% CO_2 in air, control and TPA-treated cells were collected, washed twice in cold RPMI, and processed for RNA extraction as described below. Control and TPA-treated myeloid cells were stained for sodium fluoride (NaF) inhibitable naphthyl-acetate-esterase (α-NAE) and napthol-ASD-chloroacetate esterase (N-ASD-CAE) as previously described.[20] The percentage of adherent cells in myeloid leukemic cells following TPA exposure was evaluated as previously reported.[21] U-937 cells were maintained in RPMI 1640 complete medium and subcultured twice weekly.

Immunophenotypic characterization of leukemic cells. Leukemic cells were characterized by a panel of monoclonal antibodies (MoAbs) either immediately after Ficoll purification or after culture in the presence or absence of TPA. MoAbs recognizing antigenic specificities of different blood cell lineages and grouped into "clusters of differentiation" (CD) according to criteria of the III International Conference and Workshop on Leukocyte Antigens (Oxford, 1986) were either a gift of Dr G. Rovera from Wistar Institute, Philadelphia (S5.25, S5.7)[22] or were obtained through commercial sources: OKM1, OKB2, OKT11, OKT6, OKT8, OKT3, OKT4 (Ortho Pharmaceuticals Corp, Raritan, NJ); anti-HLA-DR, Leu-10 (HLA-DQ), Leu-1, anti-IL-2R (interleukin 2 receptor), anti-TrR (transferrin receptor) (Becton Dickinson Co, Sunnyvale, CA); B4, MO2, MY7, MY9 (Coulter Immunology, Hialeah, FL); BA-2 (p24 Ag), 33.1 (HLA-DQ), BA-3 (CALLA) (Hybritech Inc, San Diego); fluorescein-conjugated (FITC)-conjugated goat $(FAB')_2$ antihuman Ig, IgA, IgM, IgD, IgG, k (Kallestad, Austin, TX). In all cases 0.5×10^6 leukemic cells in a volume of 100 μL were incubated at 4°C for 30' with different MoABs at the appropriate dilution. Cells were then washed three times with phosphate-buffered saline (PBS) and incubated at 4°C for an additional 30' with FITC-conjugated goat antimouse Ig (Ortho). After three more washings in PBS cells were analyzed by means of a flow cytometer (Ortho, Spectrum, IL). For cytoplasmic Ig (CyIg) analysis, cytospin preparation were fixed in methanol/acetone (3:1) for 5' at -20°C prior to FITC-conjugated goat antihuman IgM application. Cells were then observed under an epifluorescence UV microscope (Zeiss).

RNA extraction and hybridization. Total cellular RNA was extracted from leukemic cells either soon after Ficoll purification or after 30' and 24 hours of culture in the presence of 20 ng/mL TPA by the guanidium hydrochloride method.[23] Total RNA (5 μg/lane) was fractionated on 1% agarose gel containing 2.2 mol/L formaldehyde in MOPS buffer and transferred onto nitrocellulose filter.

The RNA bound to nitrocellulose was prehybridized for four hours at 42°C (in 1% glycine, 40% formamide, 5X SSC, 50 mmol/L NaH_2PO_4 pH 6.5, 250 μg/mL sonicated salmon sperm DNA, 1X Denhardt's solution and hybridized for 12 to 16 hours at 42°C (in 50% formamide, 2X SSC, 40 mmol/L NaH_2PO_4 pH 6.5, 200 μg/mL salmon sperm DNA, 10% dextran sulphate, 10 mmol/L EDTA, 0.1% SDS) with 3×10^6 cpm of ^{32}P nick-translated purified DNA fragments (2×10^8 cpm/μg of DNA). The oncogene-specific probes used were *v-fos* (pBR322 1.0 Kb PstI insert)[24] and v-ras (clone HiHi 3 pBR322 1.0 Kb Hinc II fragment).[25] The size of the *c-fos* transcripts was determined relatively to 18S and 28S rRNA markers, which were assumed to correspond to 1.8 and 4.5 Kb, respectively. For dot-blot hybridization studies different amounts of total cellular RNA were denatured and diluted in 10X SSC and spotted onto nitrocellulose by means of a dot-manifold apparatus (Schleicher & Schuell). Filters were than baked and hybridized to 6×10^6 cpm of oncogene-specific ^{32}P nick-translated probes as described for Northern blots. Filters were washed two times in 2X SSC at room temperature for 20 minutes, two times in 0.5X SSC, 0.1% sodium dedecyl sulfate (SDS) at 50°C for 30 minutes, and finally four times in 2X SSC at room temperature for ten minutes. Levels of *c-fos* RNA were expressed as arbitrary units (au) relative to the levels of *c-fos* RNA present in uninduced U-937 cell line set arbitrarily to 1.0. The specificity of the hybridization experiments with the *c-fos* probe and the possibility of RNA miscalibration or of a TPA-induced aspecific increased or decreased transcription were assessed by hybridizing the same blots with a different probe specific for the *c-ras*^{ki} oncogene that represented the internal calibration of the system.

RESULTS

Basal expression of the c-fos *oncogene in myeloid cells.* Constitutive expression of *c-fos* oncogene in human myeloid cells was investigated by evaluating the presence of *c-fos*-specific transcripts in leukemic samples from 16 patients with various forms of ANLL. An example of dot-hybridization assay of RNA extracted from myeloid leukemias is shown in Fig 1. Cells obtained from leukemia subtypes FAB M4 and M5 expressed levels of *c-fos* up to tenfold higher than those detectable in other FAB subtypes. Conversely *c-ras*^{ki} expression did not show any significant variation among the different leukemia samples (Fig 1).

In Table 1 relative levels of *c-fos* expression in all the 17 leukemic samples (both peripheral blood and bone marrow were examined in patient No. 2) are reported, along with α-NAE activity and OKM1/CD11b and MO2/CD14 MoAbs binding. The range of *c-fos* expression within the AMML/AMol group (FAB M4, M5) varied from 3.8 to 9.9 au. On the other hand, pure granulocytic leukemias (FAB M1, M2, M3) and the two erythroleukemic samples (FAB M6) studied expressed lower levels of *c-fos* transcripts (0.2 to 1.9 au).

By comparing the levels of *c-fos* expression with the differentiation markers on leukemic cells, it appears that there was a strong correlation between the presence of "true" monocytic markers (α-NAE and MO2/CD14) and high

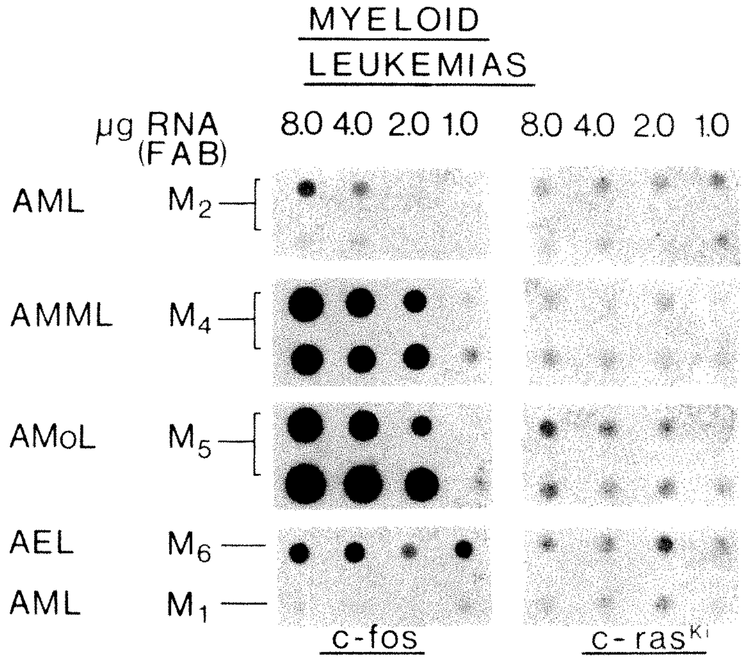

Fig 1. Basal levels of *c-fos* and *c-ras*^{ki} oncogene expression in human myeloid leukemia cells as detected by dot-blot hybridization. RNAs were obtained from the following samples (see Table 1): AML FAB M2 (patient no. 1, patient no. 2/PB), AMML FAB M4 (patient no. 8, patient no. 10), AMoL FAB M5 (patient no. 11, patient no. 14), AEL FAB M6 (patient no. 15), AML FAB M1 (patient no. 3). For details on RNA isolation and hybridization, see Materials and Methods.

†Percent of positive cells. Fresh leukemic cells were analyzed soon after Ficoll purification.

‡Levels of RNA quantitated by dot-blot hybridization followed by densitometric scanning of autoradiographic spots and expressed as arbitrary units (au) relative to the levels of *c-fos* RNA present in uninduced U-937 cell line set arbitrarily to 1.0. Values > 2 au are encased.

levels of *c-fos* expression. On the contrary, no correlation was found between *c-fos* expression and the panmyeloid antigen (CD11b) recognized by the OKM1 antibody. The restriction of constitutive *c-fos* expression to cells belonging to the monocytic lineage indicates that basal levels of *c-fos* transcription might be directly related to the presence on leukemic cells of monocyte-restricted markers such as sodium fluoride inhibitable α-NAE and the binding of the MO2/CD14 antibody.

Basal expression of c-fos *oncogene in lymphoid cells.* *c-fos* expression was evaluated as described for myeloid cells; an example of dot-blot hybridization of RNA from lymphoid malignancies with a *v-fos* and a *v-ras*^{ki} probe is shown in Fig 2. *c-ras*^{ki} RNA levels did not show any appreciable variation among the different leukemias examined. On the contrary, some of the samples revealed levels of *c-fos* expression up to sixfold higher than those detectable in other leukemic cells of the same subtype. In Table 2 relative levels of *c-fos* expression in all the 17 samples of lymphoid leukemias studied are shown, along with the phenotypic characterization performed with MoAbs against lymphoid and myeloid antigens. Low levels of *c-fos* expression (≤2 au) were detected in 11 of 17 samples without specific distribution relatively to the lineage or stage of differentation. Higher levels, comparable to those of myelomonocytic leukemias, were observed in six cases, all of B lineage. Among those, B CLL patients No. 26 and 27 displayed, together with lymphoid markers, at least four monocytic antigen (OKM1/MO1/CD11b, MY7/CDw13, and MY4/CD14); the pre-pre B leukemia harboring the t(4;11) translocation, patient No. 20, showed positivity for four monocytic markers (OKM1/MO1/CD11b, MY9/CD36, MY7/CDw13) and α-NAE. Cells from a patient with HCL displaying positivity for the OKM1 and Leu-M5 markers also highly expressed *c-fos* transcripts. Among lymphatic leukemias without concomitant expression of monocytic markers, high level of *c-fos* transcripts

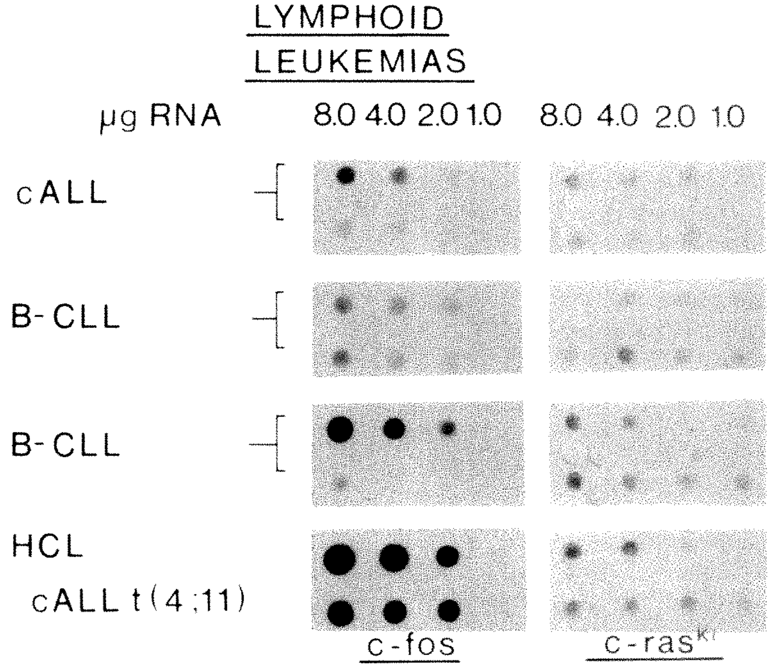

Fig 2. Basal levels of *c-fos* and *c-ras*^{ki} oncogene expression in human lymphoid leukemia cells as detected by dot-blot hybridization. RNAs were obtained from the following samples (see Table 2): cALL (patient no. 18, patient no. 19), B CLL (patient no. 24, patient no. 25), B CLL (patient no. 26, patient no. 23), HCL (patient no. 29), CALL t(4,11) (patient no. 20). For details on RNA isolation and hybridization, see Materials and Methods.

were detected only in the most immature of the cases examined, ie, a B-committed ALL (patient No. 17) and in cells from a PLL (patient No. 28). Both acute and chronic T lymphoid leukemias showed a *c-fos* expression slightly higher than uninduced U-937 cells (<2.0 au).

c-fos *expression during TPA-induced monocytic and lymphoid differentiation.* Cells from 22 patients with different forms of leukemias (Table 3) were exposed in vitro to 20 ng/mL TPA, and total cellular RNA was extracted at 30′ and 24 hours and hybridized to *fos* and *ras*^{ki} probes. Specific

*Relative levels of *c-fos* RNA in leukemic cells exposed for 30 minutes and 24 hours to 20 ng/mL TPA. RNA levels have been quantitated by densitometric scanning of autoradiographic films and are expressed as folds of increase relatively to the levels of uninduced cells (ie, cells cultured for 30 minutes and 24 hours in TPA-free medium).

†t(4,11) translocation.

RNA levels were analyzed by Northern blotting hybridization and quantitated by densitometric scanning of dot-blot autoradiographic films and expressed as times of increase relative to levels of uninduced cells. Addition of TPA to six of 8 myeloid leukemia cell cultures resulted in an overall rapid increase (up to 24.3-fold) in *c-fos* transcripts, which was maximal after 30′ and which decreased thereafter, reaching at 24 hours levels superior (twofold to 13-fold) to those of the uninduced cells (Table 3). Unexpectedly, a drastic reduction of *c-fos* transcripts following TPA treatment was observed in cells from patients No. 3 (FAB M1) and No. 11 (FAB M5). A representative Northern blot showing the major specific 2.2 Kb *c-fos* band in FAB M2 cells after TPA exposure is given in Fig 3. RNA extracted from myeloid leukemic cells at later times (up to five days) following TPA induction showed levels of *c-fos* threefold to fivefold those of uninduced cells (data not shown). *c-ras*^{ki} levels did not change significantly after TPA induction (data not shown). At three days after TPA addition, up to 70% to 90% of the cells of all myeloid leukemia patients, except patient No. 3, displayed strong adherence to plastic surface. In addition, in all AML (FAB M1, M2) and AMML (FAB M4) samples, the percentage of cells showing NaF inhibitable α-NAE activity increased sharply three days after TPA exposure, whereas N-ASD-CAE activity was reduced in all AML and AMML cells except in the case of patient No. 3. The expression of myelomonocytic differentation antigens was also modulated by TPA. The reactivity with the OKM1/CD11b and S5.25 antibodies, both reactive with late myeloid cells and mature monocytes, was in fact greatly increased in myeloid leukemia samples (FAB M2, M4, M5). The reactivity with the monocyte-restricted antibody MO2/CD14 increased in AMML/AMoL cells or was induced in AML cells following TPA treatment, whereas the expression of the immature myeloid antigen recognized by the S5.7 antibody was generally decreased (data not shown). Interestingly, as seen for the other parameters evaluated, TPA did not affect the antigenic pattern of cells from patients No. 3 and 11, whose immature phenotype remained unmodified.

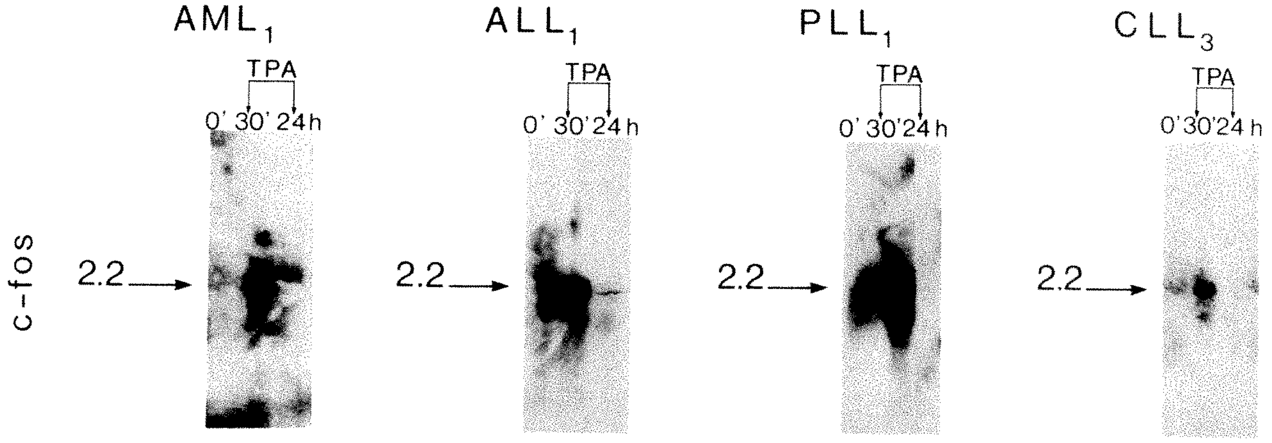

Fig 3. Expression of *c-fos* oncogene in human leukemia cells before and after TPA-induced differentiation as detected by Northern blot hybridization. RNAs were extracted after 30 minutes or 24 hours of exposure to TPA (20 ng/mL). RNAs in the 0′ lanes were obtained from cells grown for 30 minutes in TPA-free culture medium. RNAs were obtained from the following samples: AML 1 (patient no. 1), ALL 1 (patient no. 17), PLL1 (patient no. 28), and CLL3 (patient no. 25). For details on in vitro induction of differentiation, RNA isolation, blotting and hybridization, see Materials and Methods.

Treatment with 20 ng/mL TPA of cell from various forms of lymphoid leukemias resulted in a general induction of *c-fos* expression only in B cell malignancies. As the representative Northern blot in Fig 3 shows, the specific 2.2 Kb *c-fos* band, already present at high basal levels in ALL1, PLL1, and to a lesser extent in B CLL3 (patients No. 17, 28, and 25 respectively), increased after 30′ of TPA treatment and disappeared at 24 hours. Relative levels of *c-fos* expression in lymphoid leukemias quantitated from dot blots and indicated as fold of increase compared to the untreated controls are shown in Table 3. On the whole, TPA induced *c-fos* expression in nine of 11 samples of B lymphoid leukemias, whereas a drastic reduction in levels of *c-fos* was triggered by TPA in all three T cell malignancies. In the HCL cells, *c-fos* levels, already constitutively high, were unaffected by exposure to phorbol ester. The degree of induction in B cell leukemias ranged between 2.1-fold and 21-fold. After 24 hours of TPA treatment *c-fos* transcription returned to levels equal to or lower than those detected prior to induction, with the exception of cells from patients No. 20, 26, and 27.

TPA treatment also resulted in the modification of the surface phenotypes in B and T cell leukemias. Antigens of B lineage differentiation such as HLA-DR, HLA-DQ, and B4 were either increased in intensity or induced. B cell activation antigens, such as IL 2 receptor, 33.1 (DQ-like) and BA2 (p24 Ag), were all induced by TPA, whereas antigens characteristic of immature stages of B cell differentiation, such as OKB2, disappeared following treatment. These changes are suggestive of a TPA-induced differentiation of leukemic cells toward mature elements of the B lineage. The myelomonocytic markers (OKM1/MO1/CD11b, MY7/CDw13, MY4/CD14, Leu-M5/CD11d) detected in the subset of leukemias with high constitutive *c-fos* expression were similarly increased after TPA treatment along with the induction of the monocyte-restricted antigen MO2/CD14 and of markers of B lineage activation/differentiation (IL 2R, HLA-DR, HLA-DQ, BA2, and B4). The two acute T cell leukemias responded to TPA with the disappearance of the immature T lymphocyte antigen (OKT6) and with an increased intensity of the pan-T molecules T11 and T1. In the T CLL, a remarkable increase in both percentage of positivity and intensity of T11 and T1 and decreased T4 expression were induced. In all the T cell leukemias the receptor for IL 2 was strongly induced by TPA. These changes are compatible with differentiation into mature T lymphocytes.

DISCUSSION

Recent studies have suggested that the product of the *c-fos* gene may be involved in the differentiation of cells in the monocytic lineage.[12-16] High levels of *fos* transcripts have been found in primary cultures of normal murine macrophages,[12] and *c-fos* transcription and *c-fos* protein were both induced when human (U-937, HL-60) and murine (WEHI-3) leukemic cell lines were triggered to differentiate into macrophages by agents such as TPA[12,14,15] and CSF.[10] Nevertheless transient activation of *c-fos* transcription was shown to be in itself insufficient to commit U-937 cells to differentiate when stimulated by serum or diacylglycerol (DAG), and differentiation of HL-60 to macrophages by 1,25-$(OH)_2D_3$ was not accompanied by *c-fos* induction.[26] Therefore the role of *c-fos* expression in the differentiation of hematopoietic cells remains unclear. On the other hand, the definition of the lineage-specific expression of the *fos* proto-oncogene may be important in understanding hematopoietic differentiation and may provide new insights into the pathophysiology of leukemias. Consequently *c-fos* expression was studied at basal levels and after treatment with TPA in a wide variety of fresh cell from patients with different hematopoietic malignancies representing different stages and lineages of blood cell differentiation.[17,18] Our results show that a clear connection can be traced between *c-fos* expression and monocytic differentiation. In fact, high basal levels of *c-fos* transcripts were detected in myeloid leukemic cells showing markers of monocytic differentiation (FAB M4, M5), whereas very low amounts of transcripts, if any, were found in granulocytic oriented forms of myeloid leukemias (FAB M1, M2, M3) and in erythroleukemia cells (FAB M6). The expression of the monocytic-restricted antigen MO2/CD14 but not that of the panmyeloid OKM1/CD11b strongly correlated with higher *c-fos* RNA levels. This correlation was also supported by the results obtained after TPA treatment of ANLL cells in which differentiation along the monocytic pathway was accompanied by a remarkable increase in *c-fos* transcripts, resembling the kinetics of induction already described for TPA-treated U-937[15] and HL-60[14] cells. In fact, also in our hands a sustained expression of the *c-fos* gene, detectable for at least 24 hours, was found in those samples inducible to monocytic differentiation by TPA. That monocytic differentiation and *c-fos* expression are correlated was also suggested by the finding that in the two myeloid leukemic samples that did not show any differentiation in response to TPA, no increase in *c-fos* levels was induced by the phorbol ester.

The lineage-specificity of *c-fos* expression was strengthened by the low levels of constitutive expression found in lymphoid malignancies displaying pure B and T lymphocyte markers. Surprisingly, higher basal levels, comparable to those of monocytic-oriented forms of ANLL, were found in a group of lymphatic leukemia cells coexpressing B lymphocytic and myelomonocytic antigenic markers and also in the most undifferentiated form of ALL, a B-committed ALL, and the most immature form of chronic lymphoid leukemia, a PLL.

A rapid and transient *c-fos* expression was induced by TPA in almost all (nine of 11) B lymphoid samples, independently of the basal level of expression, and was accompanied by the induction of markers of B cell activation/differentiation. Yet sustained levels of *c-fos* expression were detected only in those cases within B cell leukemias in which induction of myelomonocytic markers was detected after TPA treatment.

The correlation between sustained *c-fos* expression and monocytic differentiation also seems to be confirmed by different data showing that treatment of both human leukemic cell lines and primary cultures with cytosine arabinoside and 5-aza-2′-deoxycytidine, which exert a molecular mechanism of action different from TPA, results, along with the appearance of a monocytic phenotype, in a progressive increase of steady-state levels of *c-fos* RNA, maximal three to six days after the beginning of treatment.[27] It is of interest to notice that in T cell leukemias treatment with TPA, although inducing T cell maturation, rather decreased *c-fos* expression. Since normal T cells were reported to respond to TPA with increased *c-fos* transcription,[28] our data suggest that in leukemic T lymphocytes *c-fos* expression may be regulated differently.

The finding that in fresh human leukemic cells *c-fos* expression is restricted to a monocytoid phenotype in ANLL and to a subset of B cell leukemias that express the oncogene either constitutively or following activation by TPA could suggest different interpretations. A possibility is that it represents a phenomenon of "lineage infidelity",[29] in which a subset of leukemic B cells coexpresses B lymphocytic and monocytic markers. Alternatively, the restricted *c-fos* expression in human leukemias may mirror a stage of hematopoietic differentiation in which features of monocytic and B lymphocytic lineages are physiologically and transiently coexpressed and frozen in leukemic cells.[30] It is therefore tempting to speculate that the B lymphoid disorders expressing constitutively high levels of *c-fos*, ie, ALLs with the t(4,11) translocation, HCLs, and some B-CLLs, are those that have been recognized for a long time as showing a number of monocytic features (phagocytosis, enzyme activity, differentiation antigens) along with clear B cell markers (rearranged Ig genes, pan-B antigens, IL 2 receptor).[31-36] In conclusion, our results suggest that high constitutive levels of *c-fos* RNA may identify myelomonocytic oriented forms of leukemia in addition to particular subsets of B lymphoid malignancies and some cells terminally differentiated in vitro to a monocyte-like phenotype. In this view *c-fos* expression may be regarded as an additional marker for subclassification of human leukemias.

Evidence for a Multipotential Stem Cell Disease in Some Childhood Philadelphia Chromosome-Positive Acute Lymphoblastic Leukemia

By Naoki Tachibana, Susana C. Raimondi, Stephen J. Lauer, Peggy Sartain, and Lois W. Dow

Children with Philadelphia chromosome (Ph+) acute lymphoblastic leukemia (ALL) have a poorer prognosis than do most pediatric patients with ALL. Because of this poor prognosis and the presence of the Ph chromosome, we have asked whether or not Ph+ ALL involves a multipotential stem cell. We cultured hematopoietic progenitors from two children with Ph+ ALL and examined individual BFU-E and CFU-GM colonies for the Ph chromosome. We studied cells from two patients after 18 to 34 months of first complete clinical remission; direct cytogenetic analyses showed 26% and 13% Ph+ metaphases in these patients' marrow cells. BFU-E colonies were obtained from light density marrow cells cultured in methylcellulose supplemented with erythropoietin and CFU-GM colonies from agar or methylcellulose cultures stimulated with leukocyte feeder layers. Fifty-seven G-banded metaphases were recovered from 33 colonies. Ten metaphases from seven colonies were Ph+. Ph+ metaphases were found in three of 12 and three of five BFU-E colonies from the two patients. One of 16 CFU-GM colonies from one patient had the Ph+ chromosome; analyzable metaphases were not obtained from CFU-GM of the other patient. No colonies contained both Ph+ and Ph− cells. These results indicate that Ph+ ALL with persistence of Ph+ cells in remission involves a multipotential stem cell for erythroid and granulocyte/macrophage as well as lymphoid lineages. Multipotential stem cell involvement in the pathogenesis of some childhood Ph+ ALL suggests similarities to Ph+ chronic myelocytic leukemia and may contribute to the poor prognosis of these patients.

ADVANCES in the treatment of acute lymphoblastic leukemia (ALL) have resulted in prolonged disease-free survival and cure in the majority of children with this disease.[1] However, some patients at high risk for treatment failure can be identified, including those whose blast cells contain the Philadelphia (Ph) chromosome.[2] Ph+ ALL and Ph+ chronic myelocytic leukemia (CML) share a common cytogenetic feature, but results of recent studies have demonstrated that these diseases may differ at the molecular level in alteration of the *bcr-abl* gene complex.[3-5] The persistence of the Ph chromosome in bone marrow cells from patients with Ph+ ALL in remission is a variable finding, whereas the Ph chromosome is generally found in marrow cells from patients with Ph+ CML in hematologic remission. Chromosomal abnormalities are generally absent from marrow cells from patients with Ph− ALL in remission. Previous studies of Ph− ALL have shown no evidence of nonlymphoid hematopoietic involvement in the leukemic process,[6] whereas Ph+ CML involves a multipotential stem cell for both lymphoid and myeloid cells.[7,8] To examine stem cell involvement in Ph+ ALL, we cultured bone marrow hematopoietic progenitor cells from such patients in complete clinical remission and examined mitoses from individual CFU-GM and BFU-E colonies for karyotypic evidence that might help to clarify the pathophysiology of this acute leukemia.

CASE REPORTS

Patient 1. This 4-year-old white boy presented at 12 months of age with pallor, fever, and hepatosplenomegaly. A complete blood cell (CBC) count disclosed hemoglobin 7.7 g/dL, leukocyte count of 38.8 × 10^9/L with 4% circulating blast cells, and platelet count of 41 × 10^9/L. A bone marrow aspirate showed 50% lymphoblasts, FAB-L$_1$. He had no mediastinal enlargement and CSF contained no blast cells. The marrow lymphoblasts were terminal transferase positive and had the pre-B cell phenotype with 63% of cells containing cytoplasmic immunoglobulin; the cells were positive for Ia, common acute lymphoblastic leukemia antigen (CALLA), BA-1, BA-2, Leu-16, and Leu-12 antigens. Cytogenetic studies showed five metaphases, all of which were positive for the t(9;22)(q34;q11) translocation.

Remission was induced after 4 weeks of four-drug induction chemotherapy after which he received 6 months of consolidation therapy with three rotating pairs of chemotherapeutic agents, followed by 24 months of therapy with 6-mercaptopurine and methotrexate.[9] CNS prophylaxis consisted of intrathecal methotrexate, hydrocortisone, and cytarabine. After 30 months of continuous complete remission (CCR), all therapy was stopped, and his disease has remained in CCR for an additional 8+ months. Marrow samples for in vitro studies were obtained between the 18th and 30th months of CCR.

Patient 2. This 7½-year-old white girl presented with recurrent fever, skin infections, abdominal and back pain, and hepatosplenomegaly. Laboratory studies showed anemia, thrombocytopenia, and a leukocyte count of 1,043 × 10^9/L with 46% blast cells, 2% bands, 1% metamyelocytes, 4% promyelocytes, 46% lymphocytes, and 1% monocytes. A bone marrow aspirate had 95% blast cells with a FAB-L$_2$ morphology. Spinal fluid contained 26 WBCs/mm^3 with 51% blast cells. There was no radiographic evidence of mediastinal adenopathy. The bone marrow blast cells were CALLA+ and T-3+ but negative for E rosette formation, other T cell markers, and surface and cytoplasmic immunoglobulin. Cytogenetic studies of marrow cells disclosed that all 18 metaphases analyzed were Ph+;

seven metaphases had the 46,XX,t(9;22) karyotype, and 11 metaphases showed a side line: 45,XX,−8,−E,+mar,1q−,t(9;22). The marker appears to be a derivative eight chromosome with parts of an E group chromosome and the majority of the 1q arm translocated in tandem onto the 8q. Initial therapy consisted of leukopheresis and remission-induction chemotherapy with prednisone plus vincristine and intrathecal methotrexate, cytarabine, and hydrocortisone. Because her bone marrow still contained lymphoblasts after 4 weeks of therapy, two courses of cytarabine and daunorubicin were given, and remission was induced 3 months after diagnosis. Consolidation therapy included L-asparaginase, cranial irradiation, and intrathecal methotrexate followed by continuation therapy for 30 months with pulses of adriamycin, vincristine, cytarabine, and prednisone as well as 6-MP and methotrexate. All therapy was discontinued after 30 months of CCR. Five months later she suffered a hematologic relapse. A second remission was induced and was maintained for seven months. An attempt to induce a third remission failed, and she died 47 months after diagnosis. The cell sample for in vitro study was obtained 4 months after the cessation of therapy while the patient was in first remission.

MATERIALS AND METHODS

Cell culture. Light density (<1.077 g/cc) bone marrow mononuclear cells were obtained by separation on Ficoll-Hypaque (FH) gradients. For CFU-GM assays, cells were cultured over leukocyte feeder layers in 0.3% agar or in 0.8% methylcellulose at 1×10^5 cells/mL as previously described.[10] For BFU-E, cells were incubated in 0.8% methylcellulose at 5×10^4 cells/mL with 10% leukocyte-conditioned medium and 5 units of erythropoietin/mL.[11,12] CFU-GM are reported as colonies of >50 cells on day 10 and BFU-E as colonies of >50 hemoglobin-containing cells scored on day 14. The morphological classification of cells was confirmed by examining the cytology of individually picked colonies stained with Wright's stain or 3,3′-dimethoxybenzidine.[13]

Cytogenetic analysis. Direct bone marrow cytogenetic analysis was performed as previously described.[14] Marrow cells were collected in tubes containing 8 mL of RPMI 1640 with L-glutamine, antibiotics and 30% fetal calf serum (FCS). Cells were processed immediately after a 25-minute incubation in colcemid (final concentration, 0.06 μg/mL; Gibco, Chagrin Falls, OH), rinsed twice in Hanks' balanced salt solution (HBSS), and exposed to 0.075 mol/L KCl for 32 minutes at room temperature, including periods of mixing, standing, and centrifugation. The cells were then fixed in 3:1 methanol:acetic acid for 15 minutes. Slides were prepared by using the flaming-edging technique and were allowed to age for zero to seven days.

For analysis of individual colonies, day 8-to-day 14–cultured cells were incubated for one hour with colcemid (1 μg/mL) and colonies identified microscopically as to type. Individual colonies were transferred to microtiter wells for hypotonic lysis with 0.075 mol/L KCl for 20 minutes (BFU-E) or 30 minutes (CFU-GM) and then to polylysine-treated slides.[15] Chromosomes were allowed to adhere for ten minutes, after which the excess KCl solution was removed; 3:1 methanol:acetic acid fixative was added drop-wise and the preparations flame-dried. G-banding was performed by using a modification of the trypsin-Giemsa technique of Seabright.[16] Chromosomes were identified and assigned according to the International System of Human Cytogenetic Nomenclature.[17]

RESULTS

For patients 1 and 2, respectively, six and three bone marrow aspirates were obtained during remission in the period of the in vitro studies. These marrow cells were morphologically normal with <1% blast cells. In direct cytogenetic preparations of marrow cells from patient 1, 25 (26%) of 96 metaphases were Ph+, and for patient 2, 11 (13%) of 85 were Ph+. The remaining metaphases from each patient were normal.

In vitro cultures were attempted from three aspirates from patient 1 and one aspirate from patient 2. For patient 1 the number of CFU-GM colonies scored on day 10 ranged from 42 ± 2 to 290 ± 16 per 2×10^5 plated cells and the number of BFU-E colonies from 87 ± 3 to 117 ± 5 per 5×10^4 cells. For patient 2 the sample was obtained ten days before relapse,

and growth was low with 6 ± 1 CFU-GM per 1×10^5 in methylcellulose feeder-stimulated cultures and 11 ± 1 BFU-E per 5×10^4 cells.

Cytogenetic findings in bone marrow colonies are shown in Table 1. Fifty-seven well-banded analyzable chromosome spreads were available from 16 CFU-GM colonies and 17 BFU-E colonies. From one to eight analyzable metaphases were obtained per colony. Metaphases analyzed from one of 16 CFU-GM colonies and three of 12 BFU-E colonies from patient 1 and from three of five BFU-E colonies from patient 2 (21% of all colonies studied) had the t(9;22) translocation (Fig 1). The remaining 26 colonies studied lacked this translocation.

DISCUSSION

To our knowledge this is the first report with karyotypic evidence of erythroid and granulocyte/macrophage lineage involvement in ALL. Previous studies using G6PD isozymes[6] of childhood Ph− ALL have shown no evidence of leukemic involvement by nonlymphoid cells. Similarly, results of a study of erythroid colonies from one 48-year-old patient with ALL failed to demonstrate the presence of Ph chromosome.[18] In contrast, in Ph+ CML, involvement of multiple lineages, including erythroid, myeloid, megakaryocytic, and some lymphoid cells, have been well documented.[7,8]

The Ph chromosome has been identified in 5% to 7% of childhood ALL cases[2,19] and has been associated with a poor prognosis. Children with Ph+ ALL are more likely to be older, to have elevated leukocyte counts and CNS leukemia, and to be at higher risk of remission induction failure or earlier relapse.

The Ph chromosome was initially identified in 1960[20] and was subsequently shown by Rowley[21] to result from a reciprocal translocation involving chromosomes 9 and 22. Recent molecular biology studies have indicated that the Abelson leukemia virus oncogene homologue is translocated from chromosome 9 band q34 to chromosome 22 band q11, resulting in transcription of an Abelson-derived tyrosine-kinase messenger RNA and subsequent Mr 210 protein product.[22,23] Recently it has been reported that in Ph+ ALL patients, a different Abelson-derived tyrosine-kinase with a Mr of 185 or 180 is produced.[3-5] The Abelson-related protein kinase of cells from patient 1 has a Mr of 185 (S.S. Clark and O.N. Witte, personal communication). This molecular evidence and the clinical presentation indicate that this patient has Ph+ ALL, not CML in blast crisis.

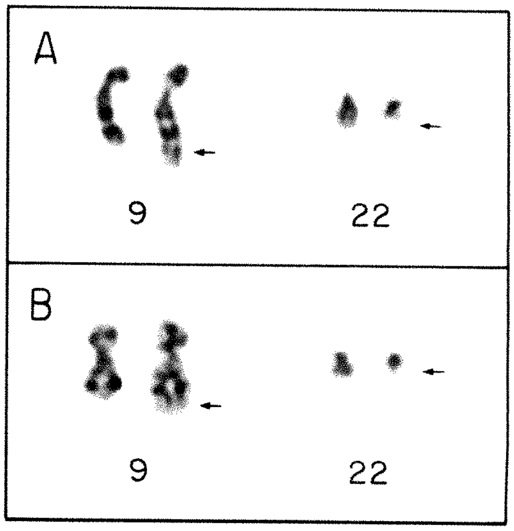

Fig 1. Partial G-banded karyotype of chromosomes involved in the t(9;22)(q34;q11) and their homologues. CFU-GM (A) and BFU-E (B) colonies from patient 1. Arrows indicate breakpoints.

In both of the patients we studied, Ph+ cells were present in their marrows during remission and appeared to be in stable mosaicism with karyotypically normal cells. Most patients who have Ph+ ALL at diagnosis have not had the Ph chromosome detected when their cells have been examined during disease remission.[2] Whether these patients have a different disease at the stem cell expression and molecular levels or an undetected mosaicism is unclear. Our study suggests that patients with Ph+ ALL may be heterogeneous and that further studies are indicated to determine lineage involvement compared to the molecular biology of these diseases.

ACKNOWLEDGMENT

We thank Roger Williams, Cecile Byars, Michael Nash, Terri F. Huddleston, Phyllis Kirchner, and Marc Valentine for excellent technical assistance; Peggy Vandiveer for typing; and Linda Daniels for editing the manuscript. For the direct cytogenetic studies we thank Dr Andrew J. Carroll and the Mayo Clinic laboratories for studies of patient 1 and Dr Patricia N. Howard-Peebles for studies of patient 2. We are grateful to Dr Steven S. Clark and Dr Owen N. Witte for making their findings available to us. These investigations were performed with the approval of the clinical trials review committee of St. Jude Children's Research Hospital.

Iron Homeostasis in β-Thalassemic Mice

By David B. Van Wyck, Manuel E. Tancer, and Raymond A. Popp

To explore the pathogenesis of nontransfusional iron overload in iron-loading anemia, we examined features of external iron exchange, internal iron kinetics, and tissue iron burden in adult mice with inherited gene-deletion β-thalassemia. Mice homozygous for β-thalassemia display moderate anemia, reticulocytosis, and shortened red cell survival, whereas heterozygous carriers appear hematologically normal. Quantitative iron determination revealed that iron content and concentration in liver, spleen, and kidney, but not heart, were far higher ($P < .01$) in 15-to 35-week old homozygous thalassemic mice than in age-matched normal and heterozygous controls; of these tissues, iron content increased with age only in kidneys ($P = .01$) of homozygous affected mice. Although plasma iron levels were only minimally elevated in homozygotes, plasma iron turnover was threefold greater ($P < .001$) than that seen in heterozygote controls. Nevertheless hyperabsorption of enteric radioiron, discernible among homozygous thalassemic mice as late as 6 to 8 weeks after birth, was not observed in older mice; additionally, thalassemic and control mice at 18 to 34 weeks showed comparable iron excretion after intravenous radioiron. We conclude that adult mice with β-thalassemia regain balanced external iron exchange, despite substantial tissue iron excess and accelerated internal iron transit.

IRON OVERLOAD is a poorly understood and potentially lethal manifestation of β-thalassemia. Patients suffering thalassemia major accumulate life-threatening iron overload after repeated red cell transfusions yet compound this transfusion-acquired iron excess with a pernicious and as yet unexplained avidity for iron contained in foods.[1] Less anemic but still troublesome[2] by their great numbers are patients with thalassemia trait, who without transfusions display evidence of iron overload in plasma iron, iron saturation, and ferritin levels measurably higher than normal.[3] Although increased gastrointestinal (GI) iron absorption and rapid internal iron turnover[4] have been demonstrated in patients with thalassemia minor,[5,6] further information about generation, maintenance, and extent of nontransfusional iron excess in carriers of the β-thalassemia gene is limited.

To explore mechanisms responsible for nontransfusional iron overload in iron-loading anemia, we examined iron balance and tissue iron levels in a recently developed model of inherited β-thalassemia in mice. The genetic defect in affected mice arises from an inheritable 3.7-kilobase (Kb) DNA deletion in mouse chromosome 7 encompassing both the regulatory and coding sequences of the gene for β-dmajor globin, a normal adult β-globin.[7,8]

Hematologic features of murine β-thalassemia depend on the number of defective genes inherited, degree of compensatory globin production, and resulting balance of α and β chain production. Among heterozygous mice bearing a single defective gene for β-dmajor globin, compensatory production of β-dminor[9] is complete, so that α and β chain synthesis remains balanced and phenotypic features normal. Among homozygotes, compensatory production of β-dminor globin is substantial but incomplete, so that synthesis of α and β chains is unbalanced (α:β synthesis ratio 1.7 in bone marrow, 1.3 in circulating reticulocytes). The associated short red-cell survival, modest anemia, microcytosis, poikilocytosis, reticulocytosis, and splenomegaly resemble β-thalassemia minor in humans.

METHODS

Experimental animals. Homozygous affected adult male mice, the offspring of homozygous breeding pairs back crossed onto a C57BL/6J background and third through fifth generation descendants of the proband male DBA/2 mouse in which a spontaneous deletion of the β-dmajor gene occurred,[7] served as test animals. For studies of GI iron absorption, groups of mice between 6 and 30 weeks old were selected; mice for all other studies were 15 to 35 weeks old. Normal C57BL/6J (Jackson Laboratory, Bar Harbor, ME) mice or heterozygous offspring of homozygote-by-C57BL/6J breeding pairs, matched for age, gender, and histocompatibility ($H\text{-}2^b$ antigen), sharing with test mice identical batches of standard chow, either Wayne Lab-Blox (iron approximately 340 μg/g; Allied Mills, Chicago) or Purina Lab Chow (iron approximately 380 μg/g; St Louis) ad libitum, served as controls. Heterozygote controls were chosen from offspring of homozygote-by-C57BL/6J pairs in preference to offspring of homozygote-by-heterozygote pairs because newborn homozygotes fail to compete successfully with nonhomozygous littermates. Similarly, mice older than 35 weeks were not examined because older homozygotes fail to thrive when compared to nonhomozygous mice of the same age. Clinical phenotype was confirmed as either normal or abnormal by hematocrit and red cell morphology, and hemoglobin genotype as normal, heterozygote, or homozygote by cellulose-acetate hemoglobin electrophoresis. After selection and matching, groups of experimental and control mice underwent studies of either plasma iron and iron-binding capacity, tissue iron levels, GI iron absorption, or plasma iron kinetics and excretion.

Blood sampling. Blood for plasma iron determination or radioiron studies was obtained by retro-orbital plexus phlebotomy using one heparinized 44.7 μL capillary pipette (Dade Diagnostics, Aguada, PR) per determination per mouse; blood for iron binding capacity was similarly obtained by filling two nonheparinized 150 μL capillary pipettes (Kimble, Toledo) per mouse; after phlebotomy, plasma was immediately separated from packed cells by centrifugation. Mice phlebotomized for iron binding capacity were excluded from further study.

Histology. Portions of tissue removed at sacrifice were examined by routine hematoxylin and eosin and trichome staining and hemosiderosis graded after Prussian blue staining.[10]

Plasma iron. After a two-hour fast, experimental and control mice underwent phlebotomy between 9 and 10 AM, and plasma iron and iron binding capacity were determined by the coulometric method[11] on a FerroChem II analyzer (Environmental Sciences Associates, Bedford, MA).

Tissue iron. After killing by decapitation, liver, spleen, kidneys, lungs, and heart were removed, dried, weighed, digested by standard methods,[12] and total iron content determined on a Perkin Elmer Model 603 atomic absorption spectrometer (Perkin Elmer, Norwalk, CT). Results were expressed as organ iron concentration (μg/mg dry weight) and iron content (μg/organ).

Metabolic cages. Mice were placed singly in plastic Nalgene (Nalge Co, Rochester, NY) metabolic cages the day prior to radioiron studies; water and powdered lab chow were provided ad libitum; stool and urine were collected separately. Preliminary experiments with these cages confirmed that experimental and control groups consume food in equal amounts and that collection of stool and urine over a seven- to 30-day period, coupled with determination of residual carcass activity, yields recovery of greater than 95% of administered radioiron activity.

Iron (Fe59 reference dose) absorption. Mice placed in metabolic cages, fasted for 16 to 20 hours, and lightly anesthetized under methoxyflurane (Metafane, Pitman-Moore, Washington Crossing, NJ), received 0.1 μCi Fe59 administered intragastrically in 0.2 mL of a solution containing ferrous sulfate (10 μg/mL) and ascorbic acid (250 μg/mL), so that each dose provided 0.03 to 0.005 μg label iron, 0.4 μg (7 nmol/L) carrier iron and 50 μg (280 nmol/L) ascorbate.[13] Activity of stool and urine collected separately for seven days thereafter was counted in a Packard Auto-Gamma scintillation spectrometer (Packard Instruments, Downers Grove, IL) with channel settings of 1.0 to 1.2 meV and results expressed as percent total dose absorbed. Radioiron for all studies was obtained as Fe59Cl (New England Nuclear, Boston, MA), specific activity >6 μCi/μg, diluted to >40 μCi/mL in 0.5 M H_2SO_4.

Iron (Fe59) kinetics in plasma. In unanesthetized mice after a two-hour fast, radioiron (0.75 μCi Fe59 as ferrous sulfate, in 0.1 mL 5% dextrose and water, providing less than 0.1 μg total iron) was administered slowly over a three-minute period via tail vein injection. In preliminary experiments, electrophoresis on nondenaturing polyacrylamide gel of plasma obtained five minutes following radioiron infusion confirmed that detectable plasma radioactivity was confined to a single band corresponding to that of purified mouse transferrin (Cooper Biochemicals, Malvern, PA). Beginning five minutes after completion of Fe59 injection and concluding five to ten minutes after the first plasma radioiron T½, five serial samples of whole blood were obtained, plasma and red cells separated immediately, and sample radioactivity determined as above. Plasma iron levels were determined on blood obtained just prior to injection. Thus total volume of blood removed in six samples approximated 300 μL whole blood per mouse. From these results plasma radioiron disappearance and T½ were obtained by linear least squares regression and plasma iron turnover (PIT; μg/dL whole blood/day) calculated according to the following formula[14]:

$$\text{PIT} = \frac{\text{Plasma Iron } (\mu\text{g/dL})}{\text{T}1/2} \times \frac{100 - .9 \times \text{Hct}}{100}.$$

Mice from these studies were then examined for radioiron excretion.

Iron (Fe59) excretion. In mice housed singly in metabolic cages after IV Fe59 injection as above, urine and stool were collected for 30 days, radioactivity determined, and results expressed as percent excretion of total injected dose.

Statistical analysis. When experiments involved three groups, differences were examined by Duncan's multiple range T test; for two groups differences were examined by Student's *t* test. Correlations were performed and significance of relationships determined by a general linear hypothesis; each test was performed using a statistical applications package[15] on an IBM-PC/AT (International Business Machines, Boca Raton, FL) configured with an 80287 math coprocessor. Results from each set of studies, including those from absorption experiments, were found to be normally distributed.

RESULTS

Tissue iron. Tissue examination in 15- to 35-week old homozygous β-thalassemic mice revealed light (1+) iron staining in liver, scattered staining in renal tubules, and heavy staining in spleen and bone marrow, without evidence of tissue damage; splenomegaly but not hepatomegaly; and, after tissue iron determination, high iron concentration and total organ-iron content (Table 1) in liver, spleen, and kidneys. By contrast, organs from age-matched heterozygous β-thalassemic mice, like those from normal C57BL/6J controls, showed no parenchymal iron histologically and low organ iron levels. Although heart weight (and therefore iron content) was lower in normal than heterozygous controls, no other differences between these groups were found by multiple range T test. Only in kidneys from homozygous thalassemic mice was there a discernible relationship between age (15 to 35 weeks) and tissue iron concentration ($r = .615$, $P = .058$) or iron content ($r = .666$, $P = .01$). In kidneys from other groups and in other organs from all three groups, correlation between age and organ-iron concentration yielded r values no greater than .281 and between age and iron content no greater than .276.

Table 2. Plasma Iron and Iron-Binding Capacity in Homozygous β-Thalassemic Mice Compared With Heterozygous Controls

	N		Age (d)	Plasma Iron (μg/dL)	TIBC (μg/dL)	Saturation (%)
Homozygous β-thalassemia	10	mean	116.0	138.7	431.3	32.2
		± SD	0.0	13.4	13.0	3.2
Heterozygous control	10	mean	117.6	112.5	399.3	28.2
		± SD	2.2	18.6	16.9	4.7
P value				.002	.000	.040

Plasma iron and iron binding capacity. Homozygous-affected mice showed plasma iron, iron-binding capacity, and percent saturation levels slightly but significantly higher than those seen in age-matched unaffected heterozygote controls (Table 2).

Intestinal radioiron absorption. GI absorption of a low-dose Fe59 standard after a 16-hour fast was significantly greater in 6- to 8-week old β-thalassemic homozygotes than in age-matched heterozygote controls; however, as age advanced absorption among homozygotes declined, so that no differences were detected in older groups of mice (Fig 1).

Plasma radioiron kinetics. After a single IV Fe59 injection, β-thalassemic homozygotes showed more rapid plasma iron disappearance (Fig 2), initial red cell iron uptake (Fig 3), and plasma iron turnover (Table 3) than age-matched (range: 18 to 34 weeks) heterozygote controls.

Intestinal radioiron excretion. Total fecal excretion of Fe59 30 days after slow IV injection was no different in seven homozygotes for β-thalassemia than in six heterozygote controls (19.5% ± 3.8% *v* 24.6% ± 8.2% injected dose, mean ± SD). No significant accumulation of radioiron was detected in urine.

DISCUSSION

Our results confirm that β-thalassemic mice, like their human counterparts, acquire substantial nontransfusional iron excess: homozygous-affected mice show tissue iron levels up to fourfold higher than normal. Liver and spleen assume most of the increased iron burden, but kidneys also show higher than normal iron levels.

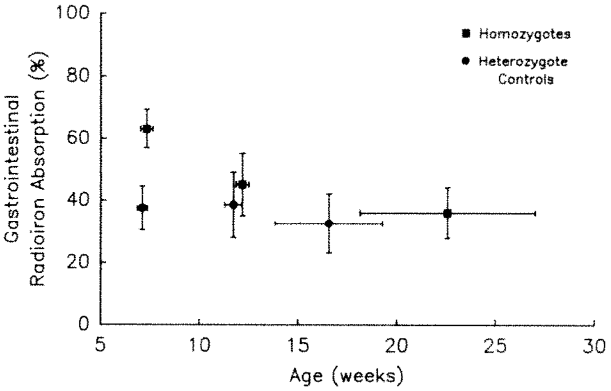

Fig 1. GI absorption of an Fe59 reference dose in homozygous thalassemic mice compared to heterozygote controls. Results represent mean ± 95% confidence intervals from age-selected groups of ten to 20 mice each. Hyperabsorption of iron was seen in homozygotes at 6 to 8 weeks of age but not in older mice.

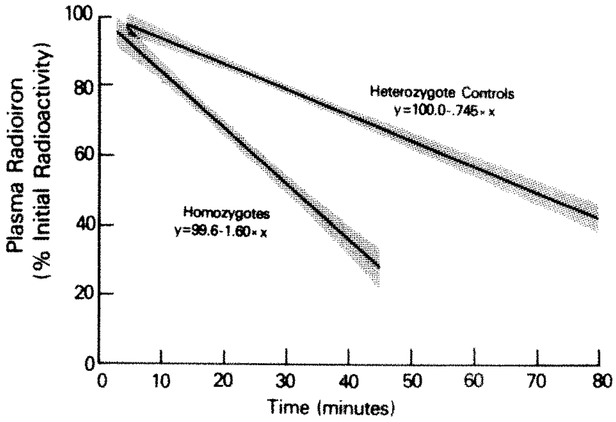

Fig 2. Plasma Fe59 disappearance early after slow IV injection in homozygous thalassemic mice compared to heterozygote controls. Results represent mean ± 95% confidence interval (shaded) from seven homozygotes and six heterozygotes, respectively; r values of individual clearance curves ranged from .96 to .99.

Despite accelerated internal iron transit, high internal iron stores, and early-occurring hyperabsorption of iron, homozygotes older than 11 to 13 weeks of age display normal GI iron absorption and fecal iron excretion and no progression of iron excess thereafter, evidence that following acquisition of iron overload early in life, adult thalassemic mice successfully regain iron homeostasis. These results suggest that spontaneous nontransfusional iron overload in thalassemia arises not from intrinsically flawed iron regulation but rather from the normal response of intact iron control mechanisms to the abnormal stimulus of increased erythropoietic activity.

The close resemblance of homozygous β-thalassemia in mice to heterozygous β-thalassemia in humans provides further evidence that the molecular origin of both the hematopoietic and iron-loading disorders is a discrete genetic defect generating unbalanced production of α and β-globin chains. Deficient production of β-dmajor chains alone fails to

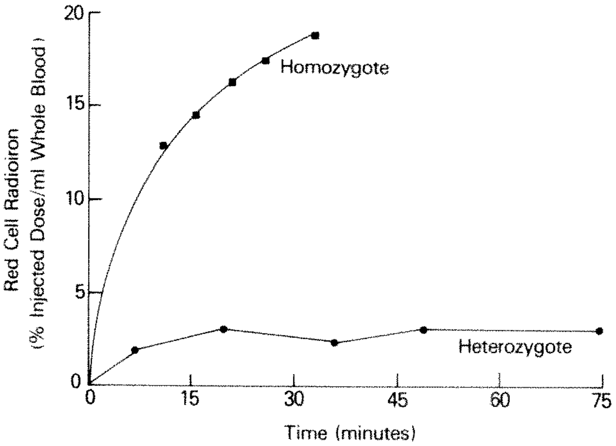

Fig 3. Representative Fe59 uptake in red cells early after IV injection in a homozygous β-thalassemic mouse compared to a heterozygous control. Within the first plasma half-life of Fe59, erythrocyte radioiron uptake was far more avid in homozygotes than in controls.

Table 3. Plasma Iron Kinetics in Homozygous β-Thalassemic Mice Compared to Heterozygous Controls

Genotype	N		Age (wk)	Body Weight (g)	Packed Cell Volume (%)	Plasma Iron Conc (µg/dL)	Plasma Iron T1/2 (min)	Plasma Iron Turnover (mg/dL whole blood/d)
Homozygote β-thalassemia	6	Mean ± SD	32.6	32.5	33.5	129.1	34.4	2.46
			5.4	3.3	3.3	35.4	5.5	.26
Heterozygote control	4	Mean ± SD	29.4	30.9	48.3	103.0	69.6	.77
			3.9	3.7	1.8	14.5	8.5	.08
P value			.340	.490	<.001	.206	<.001	<.001

account for all manifestations of the murine disorder, since heterozygous mice carry a single defective β-dmajor gene, produce lower than normal levels of β-dmajor globin, yet display red cell morphology and tissue iron levels indistinguishable from normal. Seemingly, by fully matching lost β-dmajor globin with compensatory β-dminor, heterozygotes are spared the consequences of β-dmajor gene deletion. In contrast, homozygotes, despite increased total hemoglobin production evidenced by rapid plasma iron turnover, fail to balance α and non-α globin synthesis. Whether iron loading in homozygous mice arises directly from unbalanced globin synthesis or indirectly from sustained acceleration of hematopoiesis cannot be determined from the current studies.

This relationship between phenotype and genotype facilitates experimental design: breeding heterozygotes from homozygotes on the one hand and normal mice on the other produces suitable unaffected controls for affected homozygotes, maintains a degree of genetic uniformity between experimental and control mice, yet avoids potential variation introduced by age, disease, diet, and transportation in commercially available mice.

Among tissues tested from homozygous thalassemic mice, only kidneys show a tendency to gain iron concentration and content with age. Although the relative contribution of renal iron to total body iron is low, age-related increase in renal iron may signify renal accumulation of filtered hemoglobin-bound iron after ongoing low-grade intravascular hemolysis.

Results of these studies in mice should be applied with caution to interpretation of the human disorder because iron homeostasis in small animals is distinguished from that in humans by greater potential for intestinal iron excretion,[16] greater dependence of hemoglobin synthesis on gut-absorbed rather than tissue-stored iron,[17] and exaggerated diurnal fluctuations in plasma iron levels according to feeding behavior. These considerations notwithstanding, the current results, taken together with our earlier experience in α-thalassemic mice,[18] suggest that examination of murine thalassemia may provide valuable insight into the pathogenesis of inborn errors of iron metabolism in man.

Residual Juvenile Chronic Myelogenous Leukemia Cells Detected in Peripheral Blood During Clinical Remission

By Zeev Estrov, Ian D. Dubé, Helen S.L. Chan, and Melvin H. Freedman

At diagnosis peripheral blood (PB) or bone marrow from patients with juvenile chronic myelogenous leukemia (JCML) have shown two reproducible abnormalities when studied in cell culture: impaired growth of normal hematopoietic progenitors and excessive proliferation of malignant monocyte-macrophage elements. We used these findings to assess quality of treatment response by serially studying PB specimens from four JCML patients (patients 5, 7, 8, and 9) in complete chemotherapy-induced remission. PB readily yielded high numbers of monocyte-macrophage colonies in CFU-C and CFU-GEMM assays when cultured in early remission, and the colonies were cytogenetically proven to have arisen from a malignant clone in patient 9. When studied later in remission, the abnormal cell proliferation persisted in three of the four patients, but in patient 8 PB colony growth resembled controls. Similarly, when PB from patient 8 was studied in liquid culture without using added growth factor, cell proliferation declined identical to controls, whereas PB from the other three patients showed exuberant growth of monocyte-macrophage elements. Patient 8 successfully completed therapy and has been in a long-term, disease-free remission. The other three had recurrent, ultimately fatal disease. The cell cultures have allowed detection of residual abnormal cells that circulate in PB of JCML patients in remission. Although patient numbers were small because of the rarity of JCML, the data suggested that persistence of leukemia cells in these patients had a bearing on clinical outcome.

©1987 by Grune & Stratton, Inc.

JUVENILE chronic myelogenous leukemia (JCML) is a severe progressive hematopoietic malignant disorder of infants that represents less than 1% of all childhood leukemias.[1,2] Although the long-term survival of children with acute leukemia has significantly improved,[3,4] the median survival of JCML patients is still less than 10 months.[1,2] Recent clinical trials using aggressive chemotherapy protocols have increased the complete remission rates in JCML; however, few patients have achieved long-term, disease-free survival.[5-12]

An important observation that has become a hallmark of JCML is the abnormal in vitro growth characteristics of specimens obtained from newly diagnosed patients. When cultured in semisolid systems or in liquid cultures, bone marrow (BM) or peripheral blood (PB) mononuclear cells from patients with JCML yielded excessive numbers of monocyte-macrophage colonies in the presence or absence of added growth factor.[13-15] These cell culture findings have been reliable and reproducible and have become an essential diagnostic tool for JCML in our laboratory.

Since four of our recently diagnosed patients with JCML attained complete remission with chemotherapy, we used the cell culture findings to assess the quality of treatment response by serially studying their PB specimens. The data suggested that persistence of residual leukemia cells when in remission had a bearing on clinical outcome.

MATERIALS AND METHODS

Subjects. All four patients fit the classical clinical and laboratory description of JCML.[1,2] Their data at diagnosis were reported previously in *Blood*[15] and correspond to patients 5, 7, 8, and 9 in that series. They presented with varying combinations of lymphadenopathy, skin manifestations, variable splenomegaly, pallor, and hemorrhagic signs. Most had anemia, leukocytosis, monocytosis, thrombocytopenia, and nucleated RBCs in PB. BM aspirates were cellular with granulocytic hyperplasia, monocytosis, active erythropoiesis, and reduced-to-absent megakaryocytes. All patients were treated with combined chemotherapy used for acute nonlymphocytic leukemia[16] and were followed for 12 months to 3 years. Their chemotherapy was given as described[17] and consisted of varying combinations of daunomycin, cytosine arabinoside, 5-azacytidine, VP-16-213, 6-thioguanine, and 6-mercaptopurine. These studies were performed with informed consent and were approved by the Human Experimentation Committee of our institution.

CFU-C and CFU-GEMM assays and liquid cultures. Heparinized PB cells from the four patients and PB from five healthy volunteers used as controls were layered over Ficoll-Paque (Pharmacia Fine Chemicals, Piscataway, NJ) and centrifuged (200 × g, 4°C) for 20 minutes to remove neutrophils and red cells.

The CFU-C assay was performed in methylcellulose as previously described[18] using 20% colony stimulating activity (CSA) prepared from peripheral blood leukocytes of a normal volunteer.[19] Colonies were counted after 14 days using an inverted microscope. A CFU-C colony was defined as a cluster of 20 or more cells consisting of granulocytes, monocyte-macrophages, or both. Microscopically, pure granulocytic colonies could be easily distinguished from pure macrophage colonies because of smaller cells and tighter clustering in the former.

For the liquid cultures, nonadherent PB mononuclear cells (5×10^6 cells/mL) were incubated in α-medium containing 10% fetal calf serum (FCS) for ten days as previously described.[20]

The CFU-GEMM assay was performed in methylcellulose[21,22] using 5% leukocyte-conditioned medium prepared with phytohemagglutinin (PHA-LCM),[23] human erythropoietin 1.0 U/mL (British Columbia Cancer Research Institute, Vancouver) or sheep erythropoietin 2.0 U/mL (Connaught Laboratories, Willowdale, Ontario), and 5×10^{-5} mol/L of 2-mercaptoethanol. All cultures were evaluated after 14 days for the number of BFU-E colonies, defined as an aggregate of greater than 500 hemoglobinized cells or three or more erythroid subcolonies, CFU-C colonies of granulocytic or macrophage cells or both, and mixed colonies containing all elements. Individual colonies were plucked from the cultures with a

micropipette and were analyzed for cellular composition and karyotype.

Cell characterization and cytogenetic studies. Individual colonies were plucked from cultures with a micropipette, spread on glass slides, and the cellular composition was determined microscopically using Wright's stain and nonspecific (alpha naphthyl butyrate) esterase staining with and without treatment with fluoride.[24]

The cell surface antigens of individual CFU-C colonies were assessed using the following monoclonal antibodies (MoAbs) with intestinal alkaline phosphatase as previously described[25-27]: OKIa (Ortho Diagnostic Systems Inc, Raritan, NJ) that detects HLA-D framework antigen; Leu-M3, OKM1 (Becton-Dickinson, Mountain View, CA) that identifies monocytes and macrophages; Leu-1 and Leu-4 and B1 and B4 (Becton-Dickinson) that detect T and B cells respectively. The slides were counterstained in hematoxylin, and the presence of surface antigen was indicated as bright red granular cellular inclusions seen by light microscopy. Morphological details were well preserved, and a very high degree of correlation between morphology and surface antigen expression was observed. The intensity of staining was defined as strong (+ + +), moderate (+ +), and weak (+).

BM and PHA-stimulated PB mononuclear cells were cultured for 24 and 72 hours respectively and were then harvested for cytogenetic studies by routine procedures.[28] Individual JCML CFU-C colonies were plucked for cytogenetic analysis according to published methods.[29]

Statistical analysis. The probability of significant differences between colony numbers was determined by Student's t test.

RESULTS

The four patients attained complete clinical, hematologic, and BM remission following one to four chemotherapy courses.[17] During remission all signs and symptoms of JCML disappeared, and blood counts and BM aspirates were normal.

Patient 5 was given 21 courses of chemotherapy; the remission lasted 21 months but was followed by acute myeloblastic leukemia. Patient 7 received 16 courses of chemotherapy; the remission lasted 21 months but was followed by acute myelomonocytic leukemia. Patient 9 received 9 courses of chemotherapy; JCML recurred after 11 months. Patients 5, 7, and 9 have subsequently died of progressive disease. Patient 8 received 16 courses of chemotherapy over an 18-month period, after which treatment was stopped; at the time of writing patient 8 has been in complete remission for 15 months.

PB mononuclear cells from the four patients were studied at diagnosis and serially during remission using the CFU-C assay (Table 1). At diagnosis there was excessive proliferation of CFU-C colonies compared to the controls ($P < .005$). Characterization studies of individual colonies by morphology and cytochemistry confirmed that they were comprised of monocyte-macrophage elements; 85% of the cells stained intensely for nonspecific esterase and the stain was inhibited by fluoride. Immunocytochemically, 90% of cells in JCML colonies were positive for OKIa, greater than 90% were positive for Leu-M3, and greater than 80% expressed OKM1. All cells were negative for Leu-1, Leu-4, B1 and B4.

Cultures were performed several times during remission in the four patients when WBC numbers and differential counts were normal. Representative results are shown in Table 1 at two time periods, in early clinical remission, and later while on long-term chemotherapy. Initially in early remission colony numbers were increased compared to control values, except for patient 7, and the cellular composition of the CFU-C colonies from all four was exclusively of monocyte-macrophage lineage. The cells had the identical morphological, cytochemical, and cell surface phenotype as the cells harvested from colonies at diagnosis. In contrast, control CFU-C colonies were about 50% granulocytic, 40% monocyte-macrophage, and 10% mixed lineage.

†Patients no. 5, 7, 8, and 9 were studied after 5, 4, 4, and 3 months of chemotherapy, respectively.

‡Patients no. 5, 7, 8, and 9 were studied after 20, 14, 16, and 15 months of chemotherapy, respectively.

Later in remission, while receiving chemotherapy, colony numbers were decreased or comparable to controls in patients 7 and 8 respectively but still increased in patients 5 and 9. The cellular composition of the colonies in patients 5, 7, and 9 still showed exclusive proliferation of monocyte-macrophage colonies. Results from patient 8 were different. At the conclusion of 16 months of chemotherapy, the CFU-C colonies had changed in composition and consisted of about 50% granulocytic lineage, identical to controls. Chemotherapy was stopped for patient 8 because the treatment protocol was completed, and the patient was retested seven months later while still in remission (Table 1). Colonies were somewhat reduced in number but still consisted of a normal pattern of about 50% granulocytic, 40% monocyte-macrophage, and 10% mixed lineage.

When studied at diagnosis in liquid culture without added CSA, PB cells from the four patients showed a high cellular proliferative rate compared to control PB cells. After ten days in culture, patients' cells increased numerically by approximately 70% to 150%, whereas control cells decreased by about 10%. A differential count of nonadherent JCML cells obtained on day 10 consisted of 13% monoblasts, 32% early monocytes, 54% mature monocytes, and 1% premature and fully differentiated macrophages. In the control cultures the nonadherent cells were comprised primarily of granulocytic and lymphocytic-appearing elements and a small population (less than 5%) of mature monocytes and macrophages. The majority of monocyte-macrophage cells in the control cultures were found in the adherent layer.

In remission, PB cells from patients 5, 7, and 9 still showed the abnormal, excessive proliferation of monocyte-macrophage elements in liquid culture even though routine peripheral blood cell numbers and differential counts were unremarkable. Results from patient 8 were different. After ten days of culture cell numbers decreased, and most cells became adherent to the plastic culture flasks, similar to controls.

In the CFU-GEMM assay, PB cells from the four patients at diagnosis yielded large numbers of monocyte-macrophage CFU-C colonies but absent BFU-E and mixed colony formation (Table 2). During early remission CFU-C colonies declined in number compared to the initial studies, and BFU-E and mixed colonies were detected.[15] However, CFU-C colonies in all four patients consisted of more than 90% monocyte-macrophage cells with an obvious background of individual monocytes and macrophages in the culture dishes. Cytogenetic analysis (17 metaphases) of CFU-C colonies from patient 9 showed the identical, abnormal karyotype (45,X,−Y) that was demonstrated in the diagnostic marrow, whereas concurrent analysis of PB lymphocytes showed a normal male karyotype (46,XY). Patient 5 was studied several months later while still in remission and on chemotherapy, and the CFU-C colony growth was increased and exclusively of monocyte-macrophage lineage (Table 2). Patient 8 was studied in remission 7 months after stopping chemotherapy. CFU-C numbers were decreased, and the cellular composition was approximately 50% granulocytic, similar to controls.

DISCUSSION

The unusual growth behavior of BM and PB JCML cells in vitro has facilitated characterization studies of this syndrome. In our recent study, the major finding in cell cultures of JCML BM and PB was an excessively high number of CFU-C colonies in CFU-C and CFU-GEMM culture assay systems.[15] These CFU-C colonies were comprised exclusively of monocyte-macrophage elements, as confirmed by morphology, cytochemistry, and surface marker studies, and were proven to arise from a malignant clone by cytogenetic analysis of individual colonies. The growth requirements for JCML CFU-C were also atypical because added CSA and the presence of adherent cells were not essential for JCML CFU-C to proliferate into colonies. In liquid culture JCML cells showed similar, abnormal growth characteristics and proliferated rapidly and excessively in the absence of an added humoral growth factor.[20] The clonal expansion of the malignant cells in liquid culture allowed us to perform detailed analysis of cellular lineage, functional properties, and potential for cellular differentiation.[20]

†Patient no. 5 was studied twice after 12 and 21 months of chemotherapy (upper and lower values, respectively). Patients no. 7 and 9 were studied after 10 and 13 months of chemotherapy, respectively. Patient no. 8 was studied after 16 months of chemotherapy and after being off therapy for 7 months (upper and lower values, respectively).

Thus assays for quantitation of JCML cells have become established and validated. The cell cultures have been of central importance in our laboratory for making a definitive diagnosis of this disease in new cases presenting as difficult diagnostic problems. In the present study the objective was to determine whether the assays were sensitive enough to detect small numbers of residual JCML cells from patients in chemotherapy-induced complete remissions, similar to our findings in acute lymphoblastic leukemia.[30]

The four JCML patients who were studied were all clinically and hematologically normal and hence in "complete remission." Careful inspection of PB white cell morphology by detailed differential counting did not disclose abnormal cells. Yet in all four patients studied in early remission and in three patients studied later in the treatment course, the in vitro findings were clearly abnormal in the clonogenic assays and in liquid cultures and confirmed persistent, disordered hematopoiesis. Even in studies in which colony numbers were in control range, the cellular composition of the colonies was strikingly aberrant, being exclusively of monocyte-macrophage lineage. The findings in patient 8 were different because the initially abnormal growth pattern became identical to controls with therapy. This change in the in vitro findings was clear-cut and was readily identified by several observers in our laboratory when the cultures were examined "blindly."

When tissue cultures are used to study leukemia cell proliferation, it is ideal to confirm the leukemic origin of cultured cells by demonstrating clonality. This may be accomplished by using cytogenetic markers, glucose 6-phosphate dehydrogenase isoenzymes in appropriate females, and by molecular approaches. Fortunately, JCML CFU-C from one of our patients showed a chromosomal abnormality that was previously described in this disorder.[31] Thus we were able to prove that the patient's PB clonogenic CFU-C that were detected during remission were of leukemic origin. In the other cases our data indicate that the unusual growth behavior of JCML cells in vitro can be successfully utilized to detect residual disease. This is especially important in JCML patients who do not show a marrow cell cytogenetic abnormality at diagnosis.

Thus these assays allowed identification of abnormal cells that were circulating in PB of our JCML patients in remission. An obvious question that arises is whether the finding of persistent JCML cells had prognostic significance. The answer is difficult because JCML is rare, and large numbers of patients are not available for study. However, of our four cases, the three that showed evidence of persistent, residual JCML had recurrent, fatal disease. The other case, in whom

JCML colony-forming cells were no longer detected, completed the therapy protocol and at the time of writing has been in long-term complete remission, off treatment.

The data indicate that persistence of leukemia cells in our patients had a bearing on clinical outcome. Cell cultures should be useful, therefore, in assessing the degree of efficacy of treatment programs that are designed to eradicate the disease.

The β-Globin Gene on the Chinese $\delta\beta$-Thalassemia Chromosome Carries a Promoter Mutation

By George F. Atweh, Xiao-Xiang Zhu, Howard E. Brickner, Carol H. Dowling, Haig H. Kazazian Jr, and Bernard G. Forget

A new type of $\delta\beta$-thalassemia characterized by decreased expression of the β-globin gene and increased expression of both $^G\gamma$ and $^A\gamma$ globin gene in the absence of a detectable deletion has recently been described in the Chinese population. In this study we characterize the mutant β-globin gene from this $\delta\beta$-thalassemia chromosome. An A to G transversion is identified in the "ATA" sequence of the promoter region that leads to decreased expression of the β-globin gene in vivo and in vitro. We also demonstrate the presence of this mutation in every individual with a high fetal hemoglobin phenotype in this family and its absence in every individual with a normal hemoglobin phenotype. This same promoter mutation has recently been detected in Chinese β-thalassemia genes where it is present on chromosomes of the same haplotype as that of the $\delta\beta$-thalassemia chromosome we are studying. These data support the hypothesis that an as yet unidentified mutation occurred on the ancestral chromosome carrying the promoter mutation and subsequently gave rise to the $\delta\beta$-thalassemia phenotype.

© 1987 by Grune & Stratton, Inc.

THE STUDY of the molecular pathology of the different thalassemic disorders over the last decade has uncovered an extensive array of mutations that lead to aberrant expression of one or more of the globin genes. The vast majority of the β-thalassemias have been associated with nucleotide substitutions, insertions, or deletions at regions within the β-globin gene that are of critical importance for the processes of transcription, splicing, polyadenylation, or translation of its mRNA.[1] The majority of the $\delta\beta$-thalassemias, on the other hand, are associated with extensive deletions or rearrangements within the β-globin gene cluster, which typically remove parts or all of the δ and β-globin genes along with variable amounts of flanking DNA. These deletions result in the activation of the remaining fetal globin gene(s).[1] We have recently described a new type of $\delta\beta$-thalassemia in a Chinese family characterized by decreased production of β-globin chains along with increased production of both $^G\gamma$ and $^A\gamma$ chains.[2] In the simple heterozygous state the affected individual's hemoglobin consisted of 22.3% hemoglobin F, which was heterocellularly distributed in the red cells. When this $\delta\beta$-thalassemia determinant was inherited with a β-thalassemia gene in a compound heterozygous state, the affected individual had the clinical picture of thalassemia intermedia, and his hemoglobin consisted of 15% Hb A (α_2, β_2), 3.6% Hb A_2 (α_2, δ_2), and 81.4% Hb F (α_2, γ_2). Initial gene mapping studies did not reveal any detectable deletion or rearrangement in the β-globin gene cluster. In this communication we report the structural and functional characterization of the β-globin gene on the $\delta\beta$-thalassemia chromosome of one of the individuals from this Chinese family. DNA sequence analysis of the cloned β-globin gene revealed a promoter mutation that is associated with a moderate decrease in β-globin mRNA production in a transient expression assay. We also utilized the technique of oligonucleotide hybridization to demonstrate the presence of this promoter mutation in every family member with the $\delta\beta$-thalassemia phenotype and its absence in those with a normal hemoglobin phenotype.

MATERIALS AND METHODS

β-Globin gene cloning and DNA sequence analysis. High mol wt DNA was isolated from the spleen of the compound heterozygous individual and from peripheral leukocytes of other family members using the method of Blin and Stafford.[3] The β-globin genes of the compound heterozygote were cloned as 7.5 kb *Hind III* fragments as described earlier.[4] The β-globin gene from the $\delta\beta$-thalassemia chromosome was identified by the presence of the *Ava II* restriction site in β-IVS-2 (Fig 1). This β-globin gene was subcloned as a 3.7 kb *Pst I/Bgl II* fragment in the expression vector πSVplac.[5] DNA sequence analysis was performed by the dideoxy chain termination method of Sanger et al.[6] The region of the cloned gene that was sequenced extends from 150 base pair (bp) upstream from the cap site to 200 bp downstream from the termination site, excluding 500 bp in the middle of IVS-2.

Gene expression studies. πSVplac recombinants containing the cloned mutant β-globin gene described above or a normal β-globin gene were cotransfected along with an α-globin gene containing recombinant into HeLa cells at 25% confluency using the technique of DNA coprecipitation with calcium phosphate followed by glycerol shock, as described earlier.[4] After 36 hours the cells were harvested, and cytoplasmic RNA was extracted using methods described by Favalaro et al.[7] The extracted RNA was used in S1 nuclease mapping experiments[8,9] with either a 3′ end-labeled, double-stranded probe or a uniformly labeled, single-stranded probe (see "Results" for description of specific probes). After S1 nuclease digestion, the protected DNA fragments were fractionated by electrophoresis in 6% or 8% polyacrylamide gels in the presence of 7 mol/L urea.

Oligonucleotide hybridization studies. Oligonucleotides (19 mer) specific for the −29 mutation and the normal "ATA" box region 5′ to the β-globin gene were synthesized on a DNA synthesizer (Applied Biosystems, Foster City, CA). Ten microgram samples of genomic DNA of various subjects were subjected to oligonucleotide hybridization analysis as previously described.[10,11]

The numbered arrows represent the positions of polymorphic sites that were identified by the following restriction endonucleases: 1, 4, and 5, *Hinc II*; 2, 3, and 9, *Hind III*; 6, *Taq I*; 7, *Rsa I*; 8, *Ava II*; and 10, *Bam HI*. Abbreviations: (+), cleavage; (−), absence of cleavage at a site.

RESULTS

When the DNA sequence of the cloned β-globin gene from the δβ-thalassemia chromosome was obtained and compared to the sequence of a normal β-globin gene,[12] a single nucleotide difference was detected (an A to G transversion at position −29, Fig 2). This substitution occurs within the highly conserved "ATA" box sequence in the promoter region. This same promoter mutation is the commonest β-thalassemia mutation in American blacks, where it occurs on three chromosomal haplotypes that are all different from the chromosomal haplotype of this δβ-thalassemia chromosome.[13] More recently the same mutation has been detected in three Chinese β-thalassemia genes on a chromosomal haplotype identical to the haplotype of the patient under study.[14]

The mutant β-globin gene described above and a normal β-globin gene were transfected into HeLa cells, and the cytoplasmic RNA was isolated and subjected to S1 nuclease mapping studies. When a 3′ end-labeled probe that extends from the *Nco I* restriction site at the initiation codon to the *Bam HI* restriction site of exon 2 was used (Fig 3), the same 90-nt fragment was detected in both RNAs, which corresponds to a normally spliced exon 1. However, the globin-specific mRNA accumulated in the cells transfected with the mutant gene was 85% less than that accumulated in the cells transfected with a normal β-globin gene, after correction for differences in the efficiency of transfection by normalizing to the level of expression of the cotransfected α-globin genes (data not shown). These results are in agreement with those of Antonarakis et al[13] who studied an identical mutant gene isolated from an American black patient. We also did not detect any mRNA splicing abnormalities when we used a

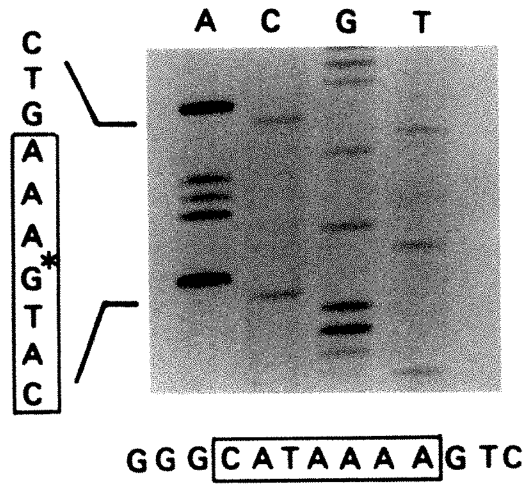

Fig 2. Autoradiograph of a DNA sequencing gel in the promoter region of the cloned β-globin gene. The normal DNA sequence is shown below the autoradiograph with the "ATA" box enclosed within the rectangle. The asterisk marks the A to G mutation within the ATA box.

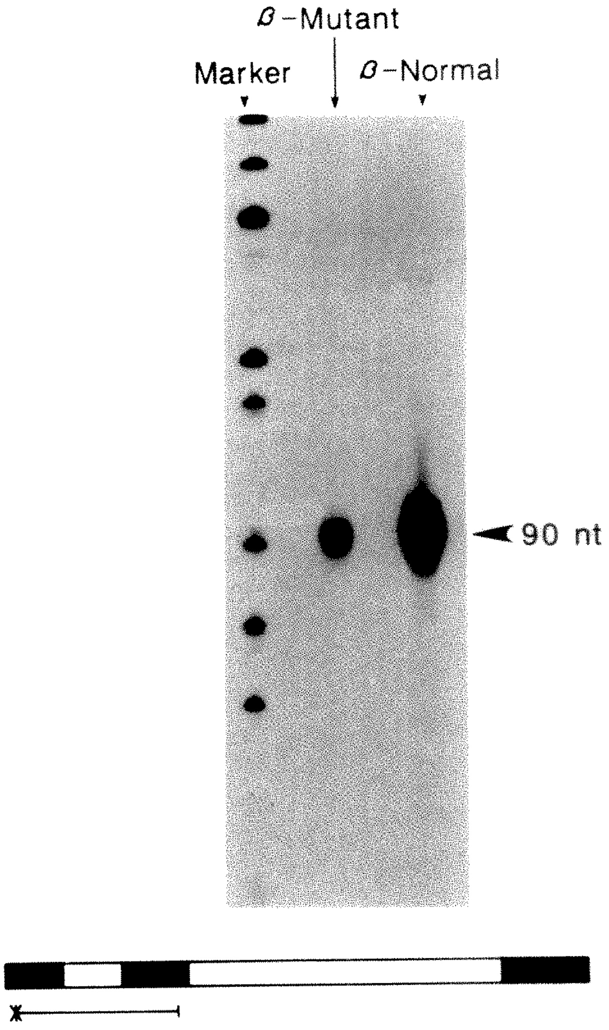

Fig 3. S1 nuclease mapping study of RNA transcribed from the β-mutant gene and a β-normal gene using a 3′ end-labeled probe represented on the schematic map below the autoradiograph. Both RNAs protect the same 90-nt fragment corresponding to exon 1. The amount of steady-state β-globin mRNA in the cells transfected with the mutant gene is 15% that of the cells transfected with the normal gene after correcting for differences in transfection efficiencies by normalizing to the level of expression of the cotransfected α-globin genes.

uniformly labeled, single-stranded probe that spans the four intron-exon junctions[4] (data not shown).

Finally, we studied the pattern of inheritance of this mutant gene in the extended Chinese family. A family pedigree is shown in Fig 4. Four of the eight family members who were available for study had a $\delta\beta$-thalassemic phenotype. Oligonucleotide hybridization analysis demonstrated that all of them had inherited the -29 promoter mutation in the β-globin gene (Fig 4). The remaining four members who did not have a $\delta\beta$-thalassemic phenotype did not inherit this mutant gene. These data provide strong evidence for the concordance of the high fetal hemoglobin phenotype and the promoter mutation in this family.

DISCUSSION

The observation that elevated levels of fetal hemoglobin seem to ameliorate the clinical severity of sickle cell anemia and homozygous β-thalassemia has sparked a great deal of interest in the study of the factors that regulate the production of fetal hemoglobin. Hereditary persistance of fetal hemoglobin (HPFH) and $\delta\beta$-thalassemia have served as prototypes of conditions in which the expression of the fetal globin genes persists at an elevated level into adult life. When the organization of the β-globin gene cluster of many individuals with these disorders was studied by gene mapping, it became obvious that numerous extensive deletions in and around the β-globin complex account for the majority of these cases. In spite of repeated efforts, the accurate mapping of these deletions has failed to convincingly demonstrate the presence of regulatory regions whose deletion may account for the increased expression of the fetal globin genes. The mechanism responsible for the activation of the fetal globin genes in those deletion disorders remains largely unknown, and different mechanisms may be operative in different types of deletion HPFHs and $\delta\beta$-thalassemias.

More recently, a few examples of HPFH that are not associated with a deletion in the β-globin cluster have become the focus of investigation. These disorders are characterized by the increased expression of either the $^{G}\gamma$ gene or the $^{A}\gamma$ gene but never both at the same time. Molecular studies of a number of these chromosomes have identified several interesting mutations in the promoter regions of either the $^{G}\gamma$ or $^{A}\gamma$ gene[15-19] that seem to be tightly linked to the HPFH phenotype.[11,20] It has been hypothesized that these mutations may be responsible for the increased expression of one or the other of the γ genes, either by increasing the binding affinity of a positive regulatory factor to the promoter region or by decreasing the binding affinity of a negative regulatory factor. Experimental support for either of these hypotheses has not yet been provided. Nonetheless these studies have provided important insight into the role of certain upstream promoter regions in the regulation of gene expression in eukaryotic cells. A single example of a nondeletion $\delta\beta$-thalassemia has been described in Sardinians where it is associated with an increase in the production of the $^{A}\gamma$-globin chains.[21,22] Molecular studies of this chromosome have demonstrated the presence of two independent mutations on the $\delta\beta$-thalassemic chromosome: a nonsense mutation at codon 39 of the β-globin gene and a promoter mutation at position -196 of the $^{A}\gamma$ gene.[23-25] When this same promoter mutation at position -196 occurs as a single mutation in Chinese or Italian individuals, the phenotype is that of $^{A}\gamma$ HPFH.[18,19]

The $\delta\beta$-thalassemia chromosome in our Chinese family is particularly interesting, since it is the only example of a nondeletion type of $\delta\beta$-thalassemia (or HPFH) where both $^{G}\gamma$ and $^{A}\gamma$ gene expression are markedly increased. The heterocellular distribution of fetal hemoglobin in simple heterozygotes and the clinical picture of thalassemia intermedia in compound heterozygotes for this determinant plus β-thalassemia have led us to classify this condition as $\delta\beta$-thalassemia rather than HPFH. We have determined that the interacting β-thalassemia gene in this family contains a previously undescribed nonsense mutation (manuscript in preparation). Since the compound heterozygote for this $\delta\beta$-thalassemia and β^0-thalassemia has 15% Hb A in his peripheral blood in the untransfused state, we conclude that the β-globin gene on the $\delta\beta$-thalassemic chromosome is active in vivo, albeit at a decreased rate.

Molecular cloning, DNA sequence analysis, and expres-

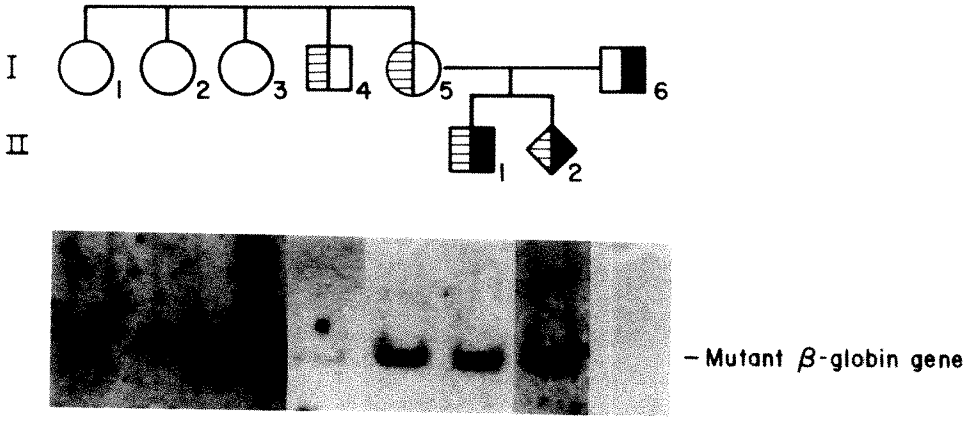

Fig 4. A pedigree of the affected Chinese family in which heterozygosity for β-thalassemia is denoted by solid black and $\delta\beta$-thalassemia by hatched circles and squares, respectively. The autoradiograph under the pedigree shows hybridization of an oligonucleotide probe specific for the -29 mutation to DNA from the different family members. Individuals I-4, I-5, II-1, and II-2 are positive for the tested mutant allele, while the remaining four individuals are negative.

sion studies of the β-globin gene on the $\delta\beta$-thalassemic chromosome identified a promoter mutation in the "ATA" box region that results in decreased expression of that gene in vitro. Study of eight individuals from this family by oligonucleotide hybridization showed a 100% concordance between this mutation and the $\delta\beta$-thalassemic phenotype. However, this does not imply that the -29 mutation is responsible for the increased expression of fetal globin genes in this situation, since the same mutation in American blacks and Chinese families is not associated with elevated levels of fetal hemoglobin. It merely provides evidence for strong linkage between the high fetal hemoglobin phenotype and the chromosome that bears this mutant β-globin gene.

We do not yet know the mechanism(s) responsible for the increased expression of fetal hemoglobin in this type of $\delta\beta$-thalassemia. As stated above, our data support the hypothesis that the mutation responsible for the high fetal hemoglobin phenotype is present in or near the β-globin gene complex. It is conceivable that two different mutations that activate the $^{G}\gamma$ and $^{A}\gamma$ genes independently may be present on the same chromosome that carries the β-globin gene with the promoter mutation. However, there is no precedent for the occurrence of three independent mutations on the same chromosome within a single gene family. Nevertheless we did rule out the presence of the -196 $^{A}\gamma$ C to T substitution[25] by oligonucleotide hybridization and that of the -202 $^{G}\gamma$ mutation[20] and -158 $^{G}\gamma$ mutation[26] by Southern blotting using the enzymes *Apa I* and *Xmn I* (data not shown). A more intriguing possibility is the occurrence of a single mutation in a regulatory region that affects the expression of both fetal genes and leads to the overexpression of the $^{G}\gamma$ and $^{A}\gamma$ genes. We also cannot exclude the possibility that a mutation in the δ-globin gene, with or without mutations in the fetal genes, may be responsible for the phenotype. The fact that the haplotypes of this $\delta\beta$-thalassemia chromosome and the β-thalassemia chromosome with the same "ATA" box mutation in the Chinese are identical supports the hypothesis that the mutation(s) responsible for the increased expression of the γ-globin genes occurred on an ancestral β-thalassemia chromosome background.

The emerging picture from the study of the different nondeletion HPFH and $\delta\beta$-thalassemia syndromes favors a model where promoter up-mutations in the fetal domain on chromosomes with a normal adult domain result in an HPFH phenotype with an almost balanced synthetic ratio of α/non-α-globin chains. On the other hand, when promoter or other regulatory up-mutations occur in the fetal domain of chromosomes that carry down-mutations in the adult domain, the resulting phenotype is that of $\delta\beta$-thalassemia with imbalanced synthetic ratios of α/non-α chains. However, it is still not clear why the expression of the structurally normal β-globin gene in the nondeletion HPFH syndromes is decreased. It has been suggested that the mere presence of the fetal domain in an active transcriptional configuration may be enough to place the adult domain in a less active configuration.[27] The experimental tools for testing this hypothesis in vivo may soon become available. It is hoped that further studies of these nondeletion syndromes may continue to unravel more of the mysteries of globin gene regulation in mammalian cells.

Further Characterization of Erythrocyte p80 and the Membrane Protein Defect of *In(Lu)* Lu(a − b −) Erythrocytes

By Marilyn J. Telen, Ian Rogers, and Michelle Letarte

We have previously shown that the *In(Lu)* gene down-regulates expression of an erythrocyte protein antigen identified by murine monoclonal antibody (MoAb) A3D8. In the present study we have examined *In(Lu)* Lu(a − b −) erythrocytes for expression of additional epitopes on the erythrocyte 80 kilodalton protein (p80) bearing the A3D8 antigen. Using a total of seven additional MoAbs that recognize three epitopes on erythrocyte p80, we have shown that *In(Lu)* Lu(a − b −) erythrocytes exhibit down-regulation of expression of all three epitopes. *In(Lu)* erythrocytes also showed a reduction in their reactivity to rabbit antibodies produced against purified p80 from either erythrocytes or lymphocytes. Furthermore the reactivity of the MoAbs was not altered by treatment of the cells with neuraminidase but was substantially reduced by treatment of cells with trypsin or chymotrypsin. The polyclonal anti-p80 sera were shown to react with a fragment of 50,000 daltons, still associated with erythrocyte ghosts, following treatment of the cells with trypsin or chymotrypsin. Treatment of erythrocytes with the thiol-reactive reagent AET decreased their reactivity with the MoAbs but had a variable effect on their reactivity with polyclonal antibodies. Erythrocyte p80 is a glycoprotein with N-linked oligosaccharides, as demonstrated by its binding to concanavalin A (Con A) and Len culinaris lectins. Following Endoglycosidase F treatment, erythrocyte p80 underwent a reduction in apparent mol wt of 11,000. The presence of a reduced amount of an intact p80 glycoprotein, seen by a decrease in reactivity with MoAbs directed at three distinct epitopes and with two different polyclonal antibodies, suggests that the *In(Lu)* gene interferes with expression by erythrocytes of the entire p80 glycoprotein.

© *1987 by Grune & Stratton, Inc.*

THE *IN(LU)* gene is an autosomal dominant gene that down-regulates but does not abolish expression of independently segregating genes encoding for the Lutheran family of erythrocyte antigens.[1,2] Once thought to be quite rare, this gene has now been shown to occur in some populations in as many as one in 3,000 donors.[3] The gene product and mode of action of the *In(Lu)* gene are not known. However, it has been recognized that the *In(Lu)* gene down-regulates expression of Lutheran antigens—which are sensitive to degradation by proteases[4] and by 2-aminoethylisothiouronium bromide[5]—and of the polysaccharide antigens P_1 and i.[6] We have also shown previously that the effect of the *In(Lu)* gene is not limited to erythrocytes.[7] Donors with the *In(Lu)* erythrocyte phenotype exhibit reduced expression of the A3D8-p80 antigen by erythrocytes as well as by a subset of leukocytes; these donors also have reduced amounts of antibody A3D8-reactive antigen in their serum.[7] The fact that the P_1 and i antigens are also down-regulated by the *In(Lu)* gene has prompted some investigators to hypothesize that the *In(Lu)* gene acts via a glycosyltransferase or blocks the activity of a glycosyltransferase.[8]

In this study we have utilized several antibodies to distinct epitopes of the p80 glycoprotein to demonstrate that the expression of all known epitopes was down-regulated by the *In(Lu)* gene.[7,9-12]

MATERIALS AND METHODS

Production of antibodies. The A3D8, A1G3, 50E6, 50C7, 50B4, 44D10, 50D7, and F10.44.2 antibodies are the products of previously described murine hybridoma cell lines.[7,9-12] Antibodies A3D8 and A1G3 have been shown to bind to nearby but nonidentical epitopes of the same protein of lymphocytes as well as of erythrocytes.[13,14] All other antibodies have been shown to bind to the same protein of lymphocytes.[14] In addition, competitive binding studies have shown that antibodies A3D8, F10.44.2, 50E6, and 50C7 bind to identical or indistinguishable epitopes[14]; antibodies 50B4, 44D10, and 50D7 bind to a second unrelated epitope on this protein.[14] Antibody A1G3 binds to a third epitope close to but not identical with that identified by A3D8 antibody.[13,14] All antibodies are of IgG1 or IgG2 heavy chain isotype.[7,9-12] Antibodies A3D8, A1G3, and F10.44.2 were used as ascites fluid diluted in phosphate-buffered saline (PBS) with 1% bovine serum albumin (BSA). Antibodies 50E6, 50C7, 50B4, 50D7, and 44D10 were used as tissue culture supernates diluted in PBS-BSA. All binding studies were done under conditions of saturating amounts of anti-p80 antibodies.

Polyclonal antiserum to erythrocyte p80 was produced by injection of rabbits with p80 isolated from erythrocyte membrane lysates by affinity to A3D8-IgG-Sepharose. On day zero, 100 μg of antigen in complete Freund's adjuvant was injected subcutaneously (SC) at three sites; on day 19 this procedure was repeated, except that Freund's incomplete adjuvant was used. Two weeks after the second injection, serum was tested for binding to erythrocytes and was found to be reactive at dilutions up to 1:1,600. All data reported were obtained with this bleed diluted 1:25 in PBS-BSA; a pre-immunization rabbit serum was used as a control in all experiments.

Rabbit antiserum to lymphocyte p80 was produced by SC injection of purified protein obtained from a detergent extract of prolymphocytic leukemia cells by 50B4-IgG-Sepharose chromatography. For the first two immunizations (day 0 and day 21), 500 μg of antigen were given SC in complete Freund's adjuvant. The third immunization, on day 56, consisted of 300 μg reduced and alkylated antigen in complete Freund's adjuvant. The animal thereafter received booster inoculations consisting of 100 μg reduced and

alkylated antigen eluted from sodium dodecyl sulfate-polyacrylamide gel (SDS-PAGE) and mixed with incomplete Freund's adjuvant. Experiments were performed with serum obtained on day 64 (bleed 3) and after the seventh injection (bleed 6). Antibody titer was measured by radioimmunoassay (RIA) using intact Lu(b+) erythrocytes. Both bleed 3 and bleed 6 saturated all binding sites at dilutions up to 1:200. Bleed 6 was reactive with reduced protein in Western blot, whereas bleed 3 was not. Binding assays were performed with saturating dilutions of antiserum (1:100) and preimmunization serum as a control.

Antibody binding assays. Erythrocyte cell surface reactivity with monoclonal antibodies (MoAbs) was measured by RIA or immunofluorescence as previously described.[7,15] Briefly, erythrocyte suspensions (5% vol/vol) were incubated 30 minutes at 4°C with dilutions of MoAbs or nonreactive control immunoglobulin (P3 × 63/Ag8 ascites or 50D6 tissue culture supernate, which contains MoAb to the HLA class II molecule).[16] Erythrocytes were then washed twice in 10 vol of PBS-BSA. For RIA, cells were resuspended to 150 μL and incubated with ^{125}I-labeled affinity purified F(ab')$_2$ antimouse Ig antibodies (Amersham Corp, Arlington Heights, IL) or ^{125}I-labeled staphylococcal protein A. Triplicate 50 μL aliquots of cell suspensions were then spun through phthalate oils (1.5 parts n-butyl phthalate [Fisher Scientific, Fair Lawn, NJ] to one part bis[2-ethylhexyl] phthalate [Eastman Kodak, Rochester, NY]). The centrifuged tubes were then clamped and cut, and the tips containing the cell pellets were counted in a gamma scintillation counter. RIA data were expressed as "Δ" cpm, as determined by the equation:

"Δ" cpm = mean cpm experimental − mean cpm control.

For immunofluorescence studies, cells were washed free of excess first antibody and then incubated with fluorescein-conjugated sheep antimouse IgG heavy and light chains (TAGO, Burlingame, CA, F/P > 6.0). After additional washes cells were resuspended in PBS-BSA and analyzed on a modified Ortho Cytofluorograf.

For analysis of the effects of proteolytic enzymes on the cell surface expression of p80 antigens, erythrocytes were treated with 2 mg/mL TPCK-trypsin (Worthington, Freehold, NJ) or chymotrypsin (Type II, Sigma Chemical Co, St. Louis) for 30 minutes at 37°C, washed three times with ice-cold PBS-BSA + 500 μg/mL soybean trypsin inhibitor, and then washed three times in PBS. Cells treated with ficin (Dr Madris Laboratories, South Hackensack, NJ) were incubated with 1 mg/mL enzyme for 30 minutes at 37°C and washed exhaustively with PBS.

Erythrocytes were treated with 12.5 U neuraminidase (from Vibrio cholerae, Calbiochem, La Jolla, CA) for 45 minutes at 37°C while suspended in Dulbecco's modified Eagle's Medium (DMEM, containing Ca^{++} and Mg^{++}) and then washed in PBS. Murine MoAb E5, which recognizes a sialic acid-dependent epitope on sialoglycoprotein β,[17] was used to assess the extent of neuraminidase digestion in these experiments.

To determine whether various p80 epitopes recognized by monoclonal and polyclonal antisera required intact disulfide bonds, erythrocytes were exposed to the thiol-reactive reagent 2-aminoethylisothiouronium bromide (AET) as previously described.[5]

After enzyme or AET treatment, cells were resuspended to 5% (vol/vol), and their level of reactivity with a series of antibodies was measured by RIA as above. Data given (Table 1) are either from a representative experiment (when three or more were performed) or represent the mean of two experiments. Aliquots of cells were also used to prepare membrane ghosts for immunoblotting experiments (see below).

Rare *In(Lu)* Lu(a−b−) erythrocytes were obtained from an inventory of frozen rare erythrocytes of the Duke Medical Center Immunohematology reference laboratory, from Dr M.N. Crawford[1] (Pearson Cummin Memorial Laboratory), and from Serologicals of Columbia, SC and Atlanta through the cooperation of Mary Ellen Rush and Nancy Fincher respectively. In all assays cells that were either frozen and thawed or cells that had undergone similar storage were used as Lu(b+) controls to eliminate any possible effects of age or storage on the expression of p80 antigens. At least three Lu(b+) controls were used in each experiment that examined *In(Lu)* erythrocyte antigens.

Immunochemical analysis of erythrocyte membrane proteins. Erythrocytes were washed free of serum and processed with or without enzyme treatment as described above. Erythrocytes were then made into hemoglobin-free ghosts by the method of Dodge et al[18] and solubilized in 100 mmol/L Tris, pH 6.8, 2% sodium dodecyl sulfate (SDS), 15% glycerol. Samples containing 50 μg protein were then electrophoresed through 6% to 12% linear gradient SDS-polyacrylamide slab gels (PAGE) and electrophoretically transferred to nitrocellulose paper as previously described.[5] After incubation with 3% BSA in 150 mmol/L NaCl, 10 mmol/L Tris, pH 7.4 to block nonspecific binding sites, the nitrocellulose was incubated with

subsaturating dilutions of antibody. The reactive antigen-antibody complex was then localized by binding of rabbit antimouse Ig and murine monoclonal peroxidase-antiperoxidase complexes[19] or peroxidase-conjugated goat antirabbit Ig (Sigma), followed by color development with diaminobenzidine as substrate.

Purification of erythrocyte p80. A3D8 antibody was precipitated from ascites fluid by admixture with an equal volume of saturated ammonium sulfate, pH 7.4, and conjugated to CNBr-activated Sepharose 4B (Pharmacia, Piscataway, NJ) (5 mg IgG per mL swollen gel). Ghosts were prepared from erythrocytes (washed free of serum), solubilized in an equal volume of 300 mmol/L NaCl, 10 mmol/L Na_2HPO_4, pH 7.4, 1% Nonidet P-40 (NP-40, vol/vol), 0.01% Tween 80 (wt/vol), 2 mmol/L PMSF, and centrifuged at 27,000 g for 20 minutes to remove insoluble material. A column of A3D8-Sepharose was equilibrated with a similar buffer containing 0.5% NP-40, and the soluble ghost extract was recycled through the column overnight at 4°C. The column was then washed with >5 column volumes equilibration buffer, followed by >5 column volumes 50 mmol/L Tris, pH 7.4. Elution of bound protein was accomplished with 2.5 mol/L $MgCl_2$, 50 mmol/L Tris, pH 7.4; the column was regenerated by washing with 0.1 mol/L Tris, 0.5 mol/L NaCl, pH 8.5, then 0.1 mol/L sodium acetate, 0.5 mol/L NaCl, pH 4.5, and finally 150 mmol/L NaCl, 10 mmol/L Tris, 0.1% NaN_3, pH 7.4. Eluted material was dialyzed sequentially against 50 mmol/L, 10 mmol/L, and 5 mmol/L Tris, pH 7.4 and lyophilized. Protein was then resolubilized in one-tenth volume of deionized water with 0.1% NP-40.

Lectin affinity chromatography. To assess the ability of erythrocyte p80 to bind to lentil (Lens culinaris) lectin, packed erythrocyte ghosts were mixed with an equal volume of 0.2 mol/L NaCl, 0.01 mol/L Tris-HCl, pH 7.4, 7 mmol/L $CaCl_2$ 7 mmol/L $MgCl_2$, 7 mmol/L $MnCl_2$, 0.5% NP-40 (vol/vol), 0.01% Tween 80 (wt/vol), 2 mmol/L PMSF. Lentil lectin-Sepharose 4B (Pharmacia) was equilibrated with a similar buffer containing 0.1% NP-40, and the membrane protein sample was applied to the column at room temperature. After washing the column with 5 volumes of equilibration buffer, bound proteins were eluted with equilibration buffer containing 0.1 mol/L α-methylmannoside. Eluates were concentrated by centrifugation in microconcentrators (Centricon-10, Amicon Corp, Danvers, MA).

Antigen eluted from A3D8-Sepharose was further purified by concanavalin A (Con A)-Sepharose chromatography. One hundred micrograms of protein was iodinated by incubation with 10 μg IodoGen (Pierce Chemical Co, Rockford, IL) and 1 mCi ^{125}I. The protein was then dialyzed against 0.1 mol/L Na_2HPO_4, 50 mmol/L EDTA, pH 7.0, to remove unbound ^{125}I. Radiolabeled protein was then applied to a Con A-Sepharose column (Pharmacia) equilibrated with a buffer containing 150 mmol/L NaCl, 10 mmol/L Tris-HCl, 1 mmol/L $CaCl_2$, 1 mmol/L $MgCl_2$, 1 mmol/L $MnCl_2$, pH 8.0, 0.1% Triton X-100. The column was washed in equilibration buffer until no cpm could be detected. Bound material was then eluted with a similar buffer containing 0.3 mol/L α-methylmannoside. Unbound and eluted materials were concentrated by dehydration with Aquacide (Calbiochem) and analyzed by SDS-PAGE followed by autoradiography.

Quantitation of p80 N-linked oligosaccharide. To obtain an estimate of the size of the N-linked oligosaccharides of p80 glycoprotein, Endoglycosidase F digestion was performed. Thirty-microgram aliquots of p80 purified by A3D8-Sepharose chromatography were solubilized in 0.1 mol/L sodium phosphate, 0.05 mol/L EDTA, 0.1% SDS, 1% NP-40, pH 6.1. Five units Endoglycosidase F were added to one aliquot of protein, and the enzyme-treated and control samples were incubated for two hours at 37°C. (It had previously been determined that 5 U enzyme was sufficient for a similar amount of glycophorin.) Aliquots were then mixed with SDS-PAGE sample buffer, electrophoresed, and analyzed by immunoblotting with A3D8 MoAb. For experiments performed under reducing conditions, radiolabeled p80 (approximately 13 μg per aliquot) was placed in the same buffer as above, except that 1% (vol/vol) 2-mercaptoethanol was added. Two units Endoglycosidase F were then added to one aliquot (keeping the enzyme:substrate ratio similar to that used in nonreducing conditions), and both aliquots were incubated for two hours at 37°C. Aliquots were then mixed with SDS-PAGE sample buffer, electrophoresed under reducing conditions, and the gels dried and exposed to x-ray film.

RESULTS

Characterization of epitopes recognized by antibodies to p80. We compared the effects of trypsin, chymotrypsin, and ficin treatment of intact erythrocytes on binding of A3D8, A1G3, 50E6, 50B4, and 50D7 MoAbs and on binding of polyclonal anti-p80 sera (Table 1) to determine the spatial relationships among the epitopes recognized by MoAbs and to assess the range of specificities recognized by the polyclonal antisera. Reactivity with all MoAbs was inhibited by treatment of intact erythrocytes with these proteases, indicating that there were cleavage sites for trypsin, chymotrypsin, and ficin in the extracellular domain of the protein and that cleavage at these sites destroyed the three epitopes recognized by MoAbs. The polyclonal antibodies, on the other hand, could still bind to erythrocytes after trypsin or chymotrypsin treatment, although only one polyclonal antiserum bound well after ficin treatment of red cells.

The epitopes recognized by antibodies 50B4, A3D8, and A1G3 were not sensitive to degradation by neuraminidase (Table 1). Binding of all MoAbs tested was markedly reduced by pretreatment of erythrocytes with AET, while this reagent had a more variable effect on reactivity of cells with polyclonal antisera (Table 1). The binding of rabbit anti-erythrocyte p80 to AET-treated erythrocytes was enhanced, while the binding of antilymphocyte p80 serum bleed No. 3 was decreased to 35% of normal. However, binding of antilymphocyte p80 serum bleed No. 6, obtained after several injections with dissociated, reduced and alkylated p80 glycoprotein, was decreased only 7% by AET treatment of erythrocytes. These data suggest that not all immunogenic epitopes of p80 are destroyed by AET treatment.

Binding of anti-p80 antibodies to In(Lu) *Lu(a−b−) erythrocytes.* Each of the eight MoAbs to p80 were tested quantitatively for their ability to bind to erythrocytes of Lutheran (b+) and *In(Lu)* Lu(a−b−) phenotypes by RIA, immunofluorescence-activated flow cytometry, or both, and results were compared to those obtained with multiple samples of Lu(b+) cells analyzed at the same time (Table 2). Antibodies 50E6 and 50C7, which bind to an epitope indistinguishable from that identified by antibody A3D8, were tested by RIA with nine and three *In(Lu)* samples respectively. *In(Lu)* erythrocytes exhibited a mean of 26% of normal 50E6 antibody binding, with a range of 9% to 38%. Antibody 50C7 also showed a mean of 26% of normal binding to *In(Lu)* erythrocytes (range 12% to 34%) by RIA. Antibody F10.44.2 (which also binds to an epitope indistin-

*As determined by antibody binding to erythrocytes from at least three Lu(b+) donors.

guishable from that identified by A3D8 antibody[14]) was tested for binding to Lu(b+) and *In(Lu)* erythrocytes by immunofluorescence-activated flow cytometry. The mean fluorescence channel (MFC) of *In(Lu)* erythrocytes stained with antibody F10.44.2 and fluorescein-conjugated anti-mouse antibody was 88 (on a linear scale), compared to an MFC of 357 for Lu(b+) cells, again showing that *In(Lu)* cells bound a mean of 25% (range 22% to 29%) as much anti-p80 antibody as normal cells, as measured by indirect immunofluorescence.

Antibodies 50B4, 44D10, and 50D7, which bind to an epitope on the p80 molecule unrelated to that identified by antibodies A3D8 or A1G3, were tested by RIA against Lu(b+) and *In(Lu)* Lu(a−b−) erythrocytes. *In(Lu)* erythrocytes bound 35% as much 50B4 antibody as did Lu(b+) cells and bound 45% and 39% as much 44D10 and 50D7 antibodies, respectively, as did normal cells (Table 2).

The polyclonal rabbit anti-erythrocyte p80 and rabbit antilymphocyte p80 sera were tested against samples of *In(Lu)* erythrocytes from the original *In(Lu)* proposita[1] and from her Lu(a−b−) nephew. Compared to normal Lu(b+) and Lu(a+b+) controls, the *In(Lu)* cells bound 10% as much polyclonal anti-erythrocyte p80 and 37% as much polyclonal antilymphocyte p80 (bleed 3).

Biochemical characterization of normal and In(Lu) *p80.* The erythrocyte p80 protein bound to lentil lectin, as observed for the lymphocyte protein.[10] Erythrocyte ghost proteins eluted from a lentil lectin-Sepharose affinity column contained sialoglycoproteins α and β, as well as erythrocyte p80, while sialoglycoprotein δ, as expected, was not bound to and eluted from lentil lectin (data not shown).

Fractionation of the NP-40/Tween 80 solubilized erythrocyte proteins by A3D8-Sepharose chromatography achieved isolation of p80 free from detectable contamination with glycophorins, band 3, and cytoskeletal components. As shown in Fig 1, eluted material analyzed by immunoblotting showed strong reactivity with A3D8 antibody but not with antibodies to sialoglycoproteins α, β, and δ. When an aliquot of material eluted from the A3D8-Sepharose column was radiolabeled and analyzed by SDS-PAGE under nonreducing conditions, a major band of mol wt = 80,000 was observed; a contaminating band of mol wt = 54,000 was also seen. Immunoblots of eluate stained with rabbit anti-p80 failed to demonstrate reactivity with the contaminating protein, suggesting that it was not likely a degradation product of p80. Purification of p80 away from the contaminating protein was achieved by fractionation on Con A-Sepharose (Fig 2); p80 was bound to Con A, while the contaminating protein remained in the unbound fraction.

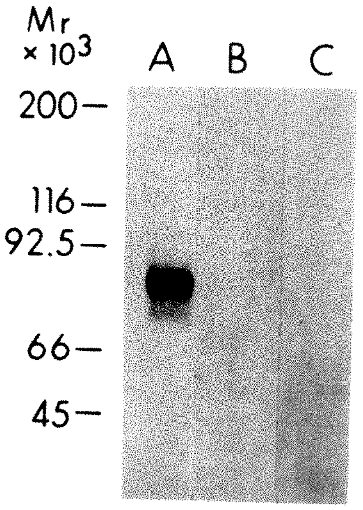

Fig 1. Immunoblot analysis of A3D8-affinity purified erythrocyte membrane protein. Erythrocyte membrane p80 was purified by A3D8-Sepharose chromatography as described in "Methods." Approximately 20 μg protein was then applied to each lane, analyzed by SDS-PAGE under nonreducing conditions, and transferred to nitrocellulose paper. Individual strips were then immunostained as described in "Methods" with MoAbs A3D8 (anti-p80, lane A), E3 (antisialoglycoproteins α and δ, lane B), and E5 (antisialoglycoprotein β, lane C). A3D8 reacted with a single protein band, while antibodies E3 and E5 failed to stain any protein.

Treatment of A3D8-purified antigen from a Lu(a−b+) donor with Endoglycosidase F showed that, if not treated with 2-mercaptoethanol, erythrocyte p80 was extremely resistant to the action of Endoglycosidase F. Under conditions that produced complete removal of the N-linked carbohydrate moiety of sialoglycoprotein α (glycophorin A), only a minor portion of the p80 was affected (Fig 3). However, removal of N-linked carbohydrate could be achieved in the presence of 2-mercaptoethanol during the enzymatic digestion. A decrease in apparent mol wt of radiolabeled erythrocyte p80 of approximately 11,000 daltons was observed following removal of N-linked oligosaccharides (Fig 3).

By using the polyclonal rabbit anti-p80 sera, we were able to demonstrate the cell-bound tryptic and chymotryptic fragments of p80 obtained following treatment of intact cells (Fig 4). Cells treated with 2 mg/mL trypsin showed a decrease in p80 but expressed a 50 kd polypeptide reactive with rabbit anti-p80. Chymotrypsin treatment produced a similar polypeptide fragment reactive with anti-p80. These fragments were unreactive with any of the MoAbs, consistent with cell binding data suggesting that all the epitopes recognized by the MoAbs resided either on the portion of the

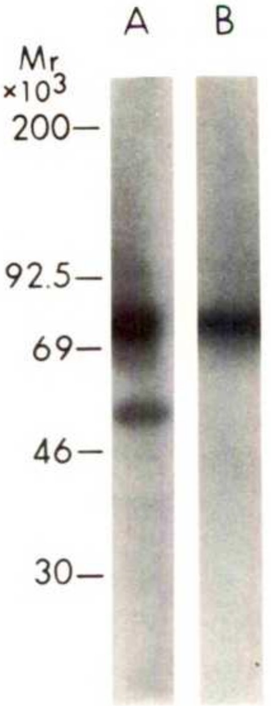

Fig 2. Analysis by radiolabeling and SDS-PAGE of the A3D8 antigen and further purification using Con A. Antigen eluted from A3D8-Sepharose was radiolabeled with ^{125}I and an aliquot analyzed by SDS-PAGE. Lane A shows the radiolabeled protein under nonreducing conditions, consisting of a major band at mol wt 80,000 and a minor band at mol wt 54,000. A portion of radiolabeled protein was then passed through a Con A-Sepharose column, as described in "Methods." SDS-PAGE analysis of the material eluted with α-methylmannoside, as shown in lane B, demonstrated a single band with mol wt = 80,000.

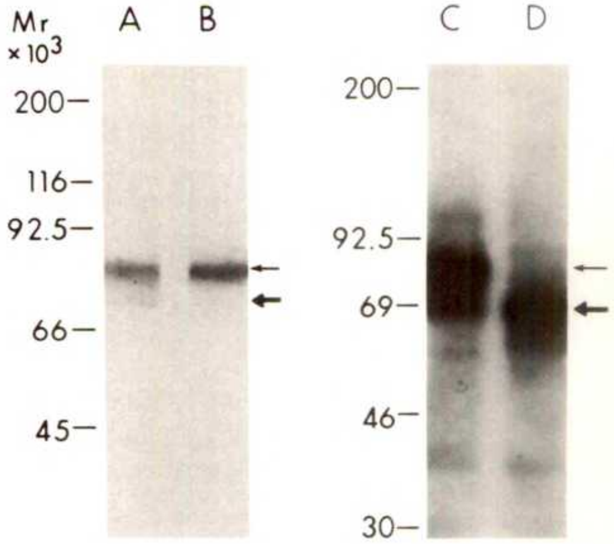

Fig 3. Endoglycosidase F digestion of erythrocyte p80. The presence of N-linked oligosaccharide on erythrocyte p80 was assessed by exposure to Endoglycosidase F. Ten micrograms of purified A3D8 antigen was incubated (in the absence of 2-mercaptoethanol) for two hours with either buffer alone (lane B) or buffer with 5 U Endoglycosidase F (lane A). Material was then analyzed by SDS-PAGE under nonreducing conditions and immunoblotted with A3D8 antibody. Only a small amount of material showed a decrease in apparent mol wt (bold arrow), while most of the protein remained intact (light arrow). However, when radiolabeled p80 protein was treated with 2-mercaptoethanol prior to Endo F digestion and analyzed by SDS-PAGE under reducing conditions, all native protein (lane C, light arrow) exhibited a reduction in apparent mol wt of about 11,000 (lane D, bold arrow).

molecule cleaved from the intact cell by these enzymes or on a portion whose secondary structure is dependent on the presence of the cleaved fragment.

Rabbit antilymphocyte p80 was used to immunoblot *In(Lu)* Lu(a−b−) erythrocyte membranes to determine whether *In(Lu)* cells contained an abnormal p80 protein not detectable with MoAbs (Fig 5). In immunoblots of normal and *In(Lu)* membrane proteins, both bleed 3 and bleed 6 rabbit antilymphocyte p80 reacted with a single glycoprotein of mol wt = 80,000 and failed to detect additional anomalous protein bands. As previously observed with MoAbs, reduced amounts of p80 were present in *In(Lu)* membrane protein extracts compared to extracts from Lu(b+) erythrocytes.

DISCUSSION

This study has shown that the *In(Lu)* gene down-regulates the expression of erythrocyte p80, as detected by MoAbs recognizing three distinct epitopes and by polyclonal antisera. *In(Lu)* Lu(a−b−) erythrocytes bound reduced amounts (10% to 45%) of each anti-p80 antibody tested when compared to Lu(b+) or recessive Lu(a−b−) cells. The fact that distinct antibodies to p80 showed somewhat different reductions in binding to *In(Lu)* erythrocytes could be due to variations in antibody affinity or actual variations in the presence of these epitopes on *In(Lu)* cells. However, because all MoAbs appear to recognize epitopes dependent on maintenance of intrachain disulfide bonds (as indicated by reduced binding to erythrocytes treated with AET), it is most likely that they bind protein determinants dependent on the secondary structure of p80. Therefore the binding data are most consistent with the hypothesis that expression of the entire p80 molecule is decreased on *In(Lu)* Lu(a−b−) erythrocytes. This hypothesis is further supported by our data that the polyclonal antisera to p80 failed to detect immunoreactive protein other than p80 in immunoblots of *In(Lu)* erythrocyte membrane proteins.

The ability of lentil lectin and Con A to bind erythrocyte p80 showed that it is a glycoprotein with N-linked oligosaccharides, as demonstrated previously for lymphocyte p80.[10] This observation is of interest because the biochemical nature of Lutheran antigens is as yet unknown and because the *In(Lu)* gene has also been reported to down-regulate expression of the P_1 and i polysaccharide antigens. It thus remains to be shown whether individual Lutheran antigens might arise from variations in amino acid sequence of a protein, variations in glycosylation, or a combination of these. Although preliminary evidence shows that Lutheran antisera immunoprecipitate and immunoblot a protein of nearly the same mol wt as does MoAb A3D8 (Telen, unpublished observations, and Parsons et al,[20] respectively), no definitive evidence is yet available regarding whether the erythrocyte protein identified by A3D8 antibody is identical

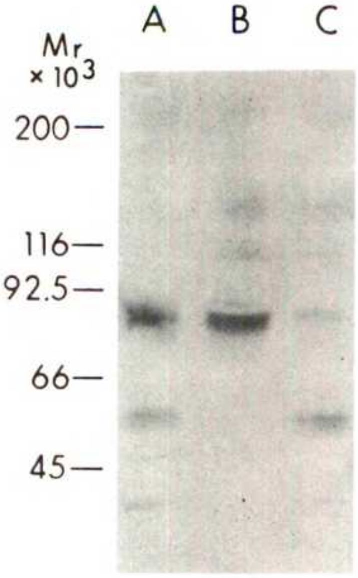

Fig 4. Cleavage products of erythrocyte p80 following protease treatment of intact cells. Erythrocytes were treated with trypsin, chymotrypsin, or buffer only, and ghosts were prepared as described in "Methods." Ghost proteins were then solubilized, analyzed by SDS-PAGE, and immunoblotted using rabbit anti-p80. Control erythrocytes demonstrated intact p80 (lane B). Cells treated with trypsin (lane A) showed residual p80 and a major fragment of mol wt 50,000, while cells treated with chymotrypsin (lane C) contained primarily a single immunoreactive peptide of mol wt 50,000.

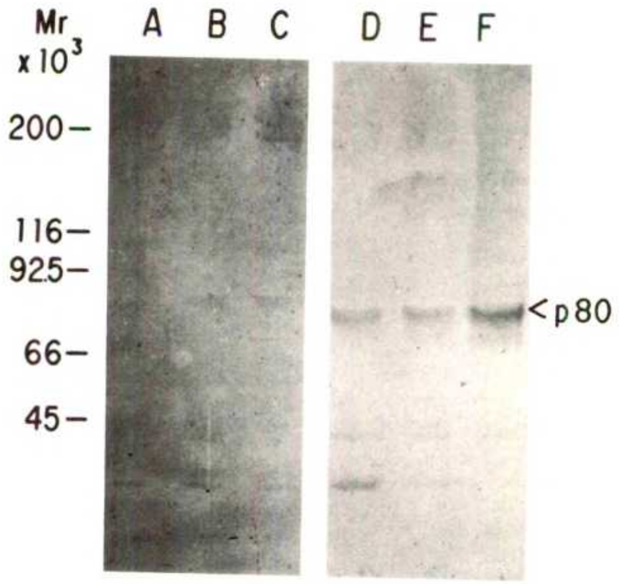

Fig 5. Immunoreactive p80 protein of Lu(b+) and *In(Lu)* erythrocytes. Ghost proteins from Lu(b+) erythrocytes (lanes C and F) and two donors' *In(Lu)* erythrocytes (lanes A and D, lanes B and E) were analyzed by SDS-PAGE and immunoblotting for presence of protein reactive with rabbit antilymphocyte p80 bleed 3 as described in "Methods." Each lane was overloaded with protein (80 μg/land) to increase sensitivity for small amounts of anomalous protein. Lanes A, B, and C were stained with preimmunization serum, and lanes D, E, and F were stained with rabbit antiserum to p80. *In(Lu)* erythrocyte ghosts contained less p80 than normal erythrocyte ghosts but did not demonstrate immunoreactive protein bands at anomalous positions on the gel. Similar results were obtained with rabbit antilymphocyte p80 bleed 6 (data not shown).

to that which binds Lutheran antisera. Ficin treatment of red cells abolished binding of p80 MoAbs but does not abrogate binding of at least some Lutheran antisera. However, these data are insufficient to determine whether these antigens reside on different proteins or at spatially distant sites on the same protein.

The fact that the *In(Lu)* gene down-regulates the expression of several epitopes on the p80 glycoprotein suggests that it is not likely to block the expression of a single oligosaccharide antigenic determinant unless the absence of such a determinant caused failure of insertion of the protein into the cell membrane. To date we have established that three distinct epitopes recognized by MoAbs were not affected by treatment of cells with neuraminidase. The *In(Lu)* gene seems to decrease the level of expression of erythrocyte p80 at the cell surface rather than lead to the production of an abnormal p80 protein. Multiple epitopes on the protein are down-regulated by the *In(Lu)* gene, while no anomalous protein is detectable in *In(Lu)* erythrocyte membrane protein. The observation that a single copy of the *In(Lu)* gene depresses expression of p80 antigens by greater than 50% suggests that the *In(Lu)* gene acts by interfering with transcription or with translation, processing, or insertion into the membrane of a normally encoded protein, whether this protein is encoded by the *in(Lu)* [normal] gene or another gene. Alternatively, the protein could be destabilized in the presence of the *In(Lu)* gene due to an abnormal interaction with another moiety resulting more directly from the action of the *In(Lu)* gene.

ACKNOWLEDGMENT

The authors wish to thank Annette Green for excellent technical assistance and Dr Mary N. Crawford for her generous gifts of blood. We are especially grateful to Drs Wendell F. Rosse, Barton F. Haynes, and Giacomo d'Agostaro for their encouragement and helpful suggestions.

Elimination of Clonogenic Stem Cells From Human Multiple Myeloma Cell Lines by a Plasma Cell-Reactive Monoclonal Antibody and Complement

By Alex W. Tong, Jennifer C. Lee, Joseph W. Fay, and Marvin J. Stone

The monoclonal antibody (MoAb) MM4 reacts with human multiple myeloma (MM) cell lines and bone marrow from patients with plasma cell dyscrasias but not with normal peripheral blood or bone marrow cells. Treatment with MM4 and rabbit complement (C′) was cytotoxic to the plasma cell-derived cell lines GM 1312, RPMI 8226, and ARH-77, as demonstrated by chromium release microcytotoxicity and trypan blue exclusion assays. The same treatment eliminated >99% of clonogenic myeloma stem cell colony formation of these cell lines, with less than 20% inhibition of normal human bone marrow pleuripotent progenitor colony formation in vitro. As an experimental model to explore the efficacy of MM4 + C′ in purging MM-involved bone marrow, normal marrow cells were mixed with RPMI 8226 or GM 1312 cells in the ratio of 90:10 or 50:50 (marrow:myeloma cells). Colony growth assays indicated that MM4 + C′ eliminated at least 2 logs of clonogenic myeloma stem cells in both 90:10 and 50:50 preparations, while sparing the majority of normal marrow progenitors (inhibition of CFU-C:10% to 13%; BFU-E:0%). The selectivity of MM4-mediated cytotoxicity may be useful for eliminating myeloma clonogenic stem cells from bone marrow of patients with multiple myeloma.

© 1987 by Grune & Stratton, Inc.

MULTIPLE myeloma (MM) represents a malignant plasma cell dyscrasia (PCD) with a wide spectrum of clinical manifestations.[1-8] In 1986 it was estimated that approximately 10,000 new patients were diagnosed with this disorder in the United States. With the use of alkylating agent chemotherapy regimens, objective remission is possible for 30% to 60% of the myeloma patient population.[8] Despite improvement in quality and duration of remission, the median survival for MM patients is limited to 3 to 4 years from time of diagnosis and has not improved substantially during the past 20 years.[1-8] MM is in the advanced stages of its natural history at time of diagnosis,[1-8] and patients responding to therapy rarely have more than a 1- to 2-log reduction (90% to 99%) of their neoplastic mass.[1,8] A large residual tumor burden, or the emergence of a drug resistant subclone,[9] accounts for the high incidence of tumor relapse. Patients with MM usually die of progressive disease, infections due to immunosuppression commonly associated with MM, or renal failure.[5-10]

Adjuvant bone marrow (BM) transplantation can provide the option of extending the dose range of cytotoxic chemotherapeutic agents to improve patient chemoresponsiveness and to prolong survival.[11] This approach has proven effective for some patients with primary hematopoietic malignancies, including refractory non-Hodgkin's lymphomas[11,12] and acute and chronic granulocytic leukemias.[12,13] Marrow transplantation studies on MM patients have been limited.[14,15] In a clinical trial of five MM patients, transplantation of syngeneic marrow accompanying massive chemotherapy extended survival.[15] However, the likelihood of success using allogeneic marrow transplantation is limited by age and/or performance considerations of the MM patient population.[1-7] Whereas appropriate monoclonal antibodies (MoAbs) can serve as tumor-purging reagents for preparing autologous BM for transplantation in other hematologic malignancies,[16-20] this approach has not been extensively investigated in MM. The majority of plasma cell-reactive MoAbs described also react with granulocytes[21-23] or lymphocytes[22-26] or do not bind the majority of patient myeloma cells.[23-26]

In a previous report[27] we described a myeloma cell-reactive MoAb, MM4, generated in this laboratory. MM4 reacted with a 40-kd antigenic determinant that was detected on seven of seven human plasma cell-derived lines and on the majority of plasma cells in all of 18 BM biopsies from patients with various plasma cell dyscrasias (MM, Waldenström's macroglobulinemia, or asymptomatic plasma cell dyscrasia). By contrast, MM4 did not react with BM biopsies or peripheral blood mononuclear (PBM) cells from patients with lymphocytic or granulocytic leukemias. The MM4-reactive antigen also was not expressed on normal PBM cells, granulocytes, or erythrocytes.[27]

In this study we examined the complement-mediated cytotoxicity of MM4 with plasma cell-derived cell lines, normal peripheral blood, and bone marrow cells. In an experimental model of normal bone marrow mixed with cells from different human MM-derived cell lines, MM4 + C′ eliminated myeloma clonogenic stem cells while preserving most normal BM progenitor cells. These observations suggest that this plasma cell-reactive MoAb may be of value for selectively eliminating myeloma cells from MM marrow ex vivo.

mia-derived ARH-77, and plasmacytoma-derived HS-Sultan lines were obtained from the American Type Culture Collection, Rockville, MD, as described previously.[27] The mouse myeloma cell line SP2/0-Ag14 was obtained from Dr Denis Burger, Portland, OR.

Patient blood and bone marrow specimens. Human PBM cells and BM samples from healthy controls or patients with hematologic malignancies were procured according to the protocol approved by the Institutional Review Board for Human Protection, Baylor University Medical Center (BUMC).

Patients with hematologic malignancies were diagnosed and classified independently by the clinical staff, Department of Oncology, Charles A. Sammons Cancer Center, BUMC. Sections of paraffin-embedded BM biopsies from these patients were obtained from the Department of Pathology, BUMC, after routine histopathologic evaluation of the specimens.

Preparation of BM + MM cell mixtures. Normal marrow mononuclear cells were derived from Hypaque Ficoll centrifugation (400 g, 20 minutes) of marrow aspirates and resuspended in RPMI 1640 at 10^6/mL.[27] For the preparation of BM + MM cell mixtures, these were mixed with appropriate volumes of either RPMI 8226 or GM 1312 cells (10^6/mL) to achieve normal marrow:myeloma cell ratios of 90:10 or 50:50.

Production of MoAbs. MM4 was generated by an alternate immunization protocol, as described previously.[27-29] Briefly, BALB/c mice were immunized alternately with 1×10^7 live cells from the RPMI 8226 and GM 1312 cell lines. Somatic hybridization of the sensitized splenocytes with SP2/0-Ag14 myeloma cells (1:1, splenocyte:myeloma cells) was performed three days after the last injection, utilizing 50% polyethylene glycol and 5% dimethyl sulfoxide according to the method of Tong et al[27-29] and Oi and Herzenberg.[30] Syngeneic thymocytes served as "filler cells" (10^6 per well) during propagation. Antibody reactivity of confluent hybridoma cultures was characterized by ELISA against MM cell lines and PBM cells from normal donors as previously described.[27-29] Selected hybrid clones were carried in vivo by injecting 2×10^7 cells intraperitoneally in pristane (2,6,10,14-tetramethylpentadecane; Aldrich Chemicals, Milwaukee)-primed BALB/c mice. MM4 from ascitic fluid was partially purified by precipitation with saturated ammonium sulfate solution and adjusted to a protein concentration of 10 mg/mL from an initial concentration of 15 to 20 mg/mL.

Reactivity of MM4 with MM cell lines and peripheral blood cells was determined by an ELISA assay.[27] Reactivity with Zenker formalin-fixed bone marrow biopsies was assessed by the immunoperoxidase assay, as described previously.[27-29]

Microcytotoxicity assay. Cytotoxicity assays were performed according to modifications of the method described by Steplewski et al[31] and others.[32,33] Target cells were labeled with sodium ^{51}chromate (New England Nuclear, Boston; 200 μCi per 2×10^6 cells, 37°C, two hours), washed twice with serum-free media, then incubated for another 30 minutes with RPMI 1640 and 10% fetal calf serum (FCS) to reduce nonspecific background radioactivity. Treatment of the washed cells (10^5/mL in RPMI 1640 + 10% FCS) with an equal volume of MM4 at the indicated final concentration was performed at 4°C (60 minutes) to minimize antigenic modulation.[34] The cells were washed once, resuspended to 10^5 cells/mL, and dispensed into a **96-well microtiter plate (100 μL/well). Complement from 3- 4-week old rabbits (Lot No. 1007; Pel-Freez, Brown Deer, WI) was** preadsorbed with human AB erythrocytes (4°C, 60 minutes) to minimize background toxicity. Incubation with complement was carried out at room temperature (100 μL per well, 23°C, 30 minutes), as defined by pilot experiments that indicated that a change of incubation temperature from 37°C reduced nonspecific toxicity without appreciably affecting MM4-specific lysis. The microtiter plate was centrifuged briefly to pellet the cells (100 g, five minutes), and half the supernatant fluid from each well was withdrawn to determine chromium release by the lysed target cells. The percent-specific lysis was determined by comparing chromium release in treated samples (CPM_{test}) with maximal release (CPM_{max}: 0.5% NP40-treated target cells), after subtraction of background (CPM_{bkg}; cells untreated with MoAb or complement), by the formula:

$$(CPM_{test} - CPM_{bkg})/(CPM_{max} - CPM_{bkg}) \times 100\%.$$

Trypan blue exclusion. The proportion of viable MM cells after MM4 + C′ treatment was determined by trypan blue exclusion.[35] Treated samples were washed once with phosphate-buffered saline (PBS), then resuspended in 200 μL of 0.5% trypan blue in saline. Viability was established by the number of cells that excluded the dye, with at least 200 cells counted in a hemocytometer.

Myeloma clonogenic stem cell assay. The clonogenic stem cell assay for cells from PCD-derived cell lines was performed according to a modified technique of Hamburger and Salmon.[36] Incubation with MM4 (4°C, 60 minutes) was performed after pelleting the tumor cells in a sterile 15-mL centrifuge tube (American Scientific Products, Dallas). The MoAb-treated cells were washed twice in RPMI 1640, incubated with rabbit complement at room temperature, then distributed in triplicates onto a 6-well culture plate (Falcon) in 0.3% agar with Iscove's modified Dubecco's medium (IMDM) and 15% FCS. The cultures were propagated in a 37°C incubator, and the number of colonies (with >50 cells) were enumerated under low magnification after seven days. The percent of growth inhibition was determined by comparing MM4-treated cultures with those treated with the same concentration of an irrelevant MoAb (SCLC 1096) that reacts with human small-cell lung carcinoma, but not with human normal peripheral blood or myeloma cells.[27,28]

BM progenitor colony formation. As a means of monitoring normal bone marrow precursor function, CFU-C and BFU-E colonies were examined in untreated and MM4 + C′-treated bone marrow preparations.[37] One hundred microliters of bone marrow mononuclear cells (5×10^5/mL) were layered onto a culture plate gelatinized with 1 mL of methylcellulose culture media (0.8% methycellulose, 20% FCS, 0.3 mmol/L 2-mercaptoethanol), and incubated at 37°C in 100% humidity, 5% CO_2, with GCT-conditioned medium (100 μL/mL; GIBCO, Grand Island, NY) for stimulating granulocytic precursor colony formation. Erythropoietin (Connaught Laboratories, Willowdale, Ontario, Canada) at a final concentration of 2.5 IU/mL was added on day 4. CFU-Cs were identified by their lack of color and relatively diffuse pattern and BFU-Es by their red color and tightly packed colonies.[37]

For the study of cell preparations containing both normal bone marrow and MM cells, myeloma clonogenic stem cells were distinguished by their larger colony size, faster growth rate, and distinctive colony morphology. GM 1312 colonies were characterized by their tightly packed spherical conformation, whereas RPMI 8226 colonies were comprised of tightly aligned tumor cells. The immunologic phenotype of cells from myeloma colonies was verified by reactivity with the plasma cell-reactive MoAbs PCA-1 (Coulter Immunology, Hialeah, FL), OKT10 (Ortho Diagnostic Systems, Boston), and MM4. Cells from myeloma colonies were removed under an inverted microscope by a drawn Pasteur pipette at day 7, deposited on slides (5×10^5 per slide) by cytospin centrifugation (Shandon Southern, Sewickeley, PA), and treated with Saccomanno fixative (50% ethanol + 2% polyethylene glycol). Reactivity with the various plasma cell-reactive MoAbs was determined by the immunoperoxidase technique.[27-29]

Limiting dilution analysis. Limiting dilution analysis of clonogenic units was determined using a Spearman estimate.[17,38] A series of ten fivefold dilutions were prepared from MM4 + C′-treated or untreated normal bone marrow preparations containing 10%

myeloma cells from the cell lines RPMI 8226, GM 1312, or ARH-77 that initially contained 5×10^5 tumor cells/mL. Five replicates (100 μL) of each dilution were plated in 6-well flat-bottomed tissue culture plates (Falcon) onto methylcellulose under the culture conditions described above. The mean value for each treatment group was estimated by:

$$M = X_o + d/2 - d/n \sum_{i=0}^{k} r_i$$

where X_o = ln initial dose = ln 10; d = ln dilution factor = ln 5; n = number of replicates per dilution = 5; k = number of fivefold dilutions = 9; and r_i = the number of wells with observed growth at the ith dilution. The estimated number of clonogenic units per milliliter was calculated as $\Theta = \exp(-0.5772 - M)$, with variance approximated by d ln 2/n.

RESULTS

MM4-mediated cytotoxicity. Cytotoxicity of MM4 and C′ against cells from established plasma cell dyscrasia (PCD)-derived cell lines was determined by short-term chromium release assays. Exposure to the IgG1 MoAb MM4 at 0.015 to 1 mg per 10^5 cells followed by rabbit C′ at the pretitered final dilution of 1:16 was cytolytic to 25% to 95% of cells from the PCD cell lines tested (Fig 1). The LD50s of MM4 + C′-mediated cytotoxicity were 0.015 mg, 0.047 mg, and 0.045 mg for GM 1312, RPMI 8226, and ARH-77 cells respectively, with a dose-response pattern of the ARH-77 line almost identical to that of RPMI 8226 (Fig 1). Toxicity to normal PBM cells (20% ± 7.5%) was evident after incubation with MM4 at 1 mg. Subsequent determinations thus were conducted at the optimal MoAb concentration of 0.5 mg/10^5 cells.

Similar to the observations of Bast[17] and others,[16,18,19] two cycles of C′ incubation (1:16 final dilution) improved cytolysis of MM4-bound tumor cells to 94.5%, 72.3%, and 80.5% for GM 1312, RPMI 8226, and ARH-77 lines respectively (Table 1). There was no appreciable increase in background toxicity by C′ alone, with a mean cytolysis of 18.75% ± 5.25% with the three cell lines tested. Under the same experimental conditions, evaluations by trypan blue exclusion demonstrated that <1% of GM 1312 cells were viable (Table 1) after MM4 + C′ treatment, despite a lower level of chromium release (94.5%). The same treatment yielded less than 6% viable RPMI 8226 cells, according to trypan blue exclusion studies. Higher background toxicity and a corresponding increase in normal BM and PBM cell lysis were observed if complement treatments were extended to three or more cycles (data not shown) or if a higher concentration of complement was used (2 × 1:8 or 1:4, Table 1). Such variations also did not result in significant improvement of cell kill, as determined by trypan blue exclusion (Table 1). Re-exposure to MM4 after complement treatment did not enhance myeloma-specific cytolysis.

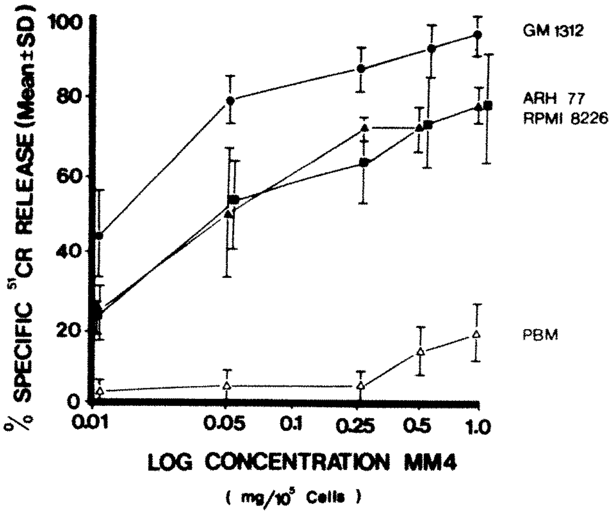

Fig 1. MM4 and complement-mediated cytolysis of MM-derived cell lines. Percent specific ^{51}chromium release by prelabeled MM cell lines GM 1312 (●), RPMI 8226 (▲), and ARH-77 (■), as well as peripheral blood mononuclear cells (PBM: △) was determined after incubation with the indicated concentration of MM4 and rabbit complement at 1:16 (see "Materials and Methods").

Depletion of clonogenic stem cells from MM cell lines. Tumor repopulation and/or metastatic growth have been postulated to be mediated by a self-renewing tumor stem cell subset. Chemoresponsiveness of clonogenic stem cell cultures of patients in vitro has been correlated with subsequent clinical response.[39-41] Previously, MM4 alone has been found to inhibit clonogenic colony formation of RPMI 8226 cells, with an LD50 of 0.01 to 0.1 mg/10^5 cells.[27] We carried out clonogenic stem cell assays to establish the effect of MM4 + C′ on clonogenic stem cells from PCD cell lines. MM4 + C′ completely abrogated myeloma clonogenic stem cell colony formation of GM 1312, RPMI 8226, and ARH-77 cell lines under optimized conditions (Table 1). The inhibition of normal marrow stem cell colony formation (CFU-C) under the same conditions was limited to 14.6% and 7.5%, after exposure to complement at 1:8 and 1:16 dilutions respectively.

Elimination of myeloma cells from bone marrow. As an experimental model to test the efficacy of MM4 + C′ in eliminating myeloma cells from involved patient marrow, cells from the RPMI 8226 or GM 1312 lines were mixed with normal bone marrow mononuclear cells in final proportions of 50:50 and 90:10 (normal marrow:myeloma cells). These ratios were designed to approximate the content of myeloma cells in BM of patients prior to treatment and in remission.

As shown in Table 2 with GM 1312 cells, the efficacy of MM4 + C′ in eliminating myeloma clonogenic stem cells from the tumor cell line was not affected by the presence of normal BM cells (Table 2). However, the overall capacity of this treatment in lysing tumor cells was diminished based on chromium release data. A mean cytolytic value of 83.8% and 59.5% of chromium-prelabeled GM 1312 cells was observed in preparations containing 90% or 10% of unlabeled BM cells respectively (Table 2).

The cytotoxic effect of MM4 + C′ on clonogenic stem cells of established MM cell lines and normal BM progenitors was examined under different incubating conditions (Figs 2 and 3). MM clonogenic stem cell colonies, enumerated at day 7, were distinguished from normal BM stem cell colonies by their characteristic colony morphology (Fig 2) and by their immunologic reactivity with plasma cell-

reactive MoAbs PCA-1, OKT10, and MM4. For preparations containing 10% myeloma cells (Fig 3 A), MM4 + C′ (1:16) consistently reduced GM 1312 clonogenic stem cell colonies by at least 2 logs (99% to 100%, n = 4). Similarly, RPMI 8226 stem cell colonies were reduced by 97% to 100% (98.6% ± 1.4%, n = 3). The same treatment inhibited 13% of normal bone marrow CFU-C but did not affect BFU-E progenitor growth. Unlike incubation of MM or BM cells alone, increase of C′ concentration to 1:8 depleted MM clonogenic stem cell colonies from both MM cell lines but did not significantly increase toxicity to BM progenitor colony formation, as measured by CFU-C and BFU-E (Fig 3 A).

Similarly, in BM preparations containing 50% MM cells (Fig 3 B), MM4 + C′ at 1:16 completely eradicated colony formation by GM 1312 and eliminated 90% (90.2% ± 14.7%, n = 3) of RPMI 8226 clonogenic stem cells. Similar to our observations on 90:10 cell mixtures, incubation with C′ at 1:8 completely inhibited RPMI 8226 clonogenic stem cell colony formation without significantly increasing toxicity to normal BM CFU-C (% inhibition: 19.7% ± 11.1%, n = 4). A slight increase in toxicity to BFU-E (% inhibition: 9.7%, n = 2) was observed at this complement concentration.

To better establish efficacy of clonogenic stem cell elimination under optimized conditions, myeloma clonogenic units in marrow preparations containing 10% myeloma cells before or after MM4 + C′ treatment were determined by limiting dilution analysis (Table 3). Two or more log reductions of clonogenic stem cell units were observed (99.4%, 98.9%, and 99.97% reduction for RPMI 8226, GM 1312, and ARH-77 cells respectively). Similar evaluation with the plasmacytoma-derived cell line HS-Sultan also demonstrated a nearly 3-log depletion of clonogenic stem cells (Table 3).

DISCUSSION

The MoAb MM4 described in this study recognizes a 40-kd antigenic determinant that is commonly expressed on normal and neoplastic plasma cells.[27] The pattern of reactivity of MM4 differs from most other previously described plasma cell-reactive MoAbs,[21-26,42] including PCA-1 and PCA-2,[21,22] R1-3,[24] B5,[25] common acute lymphoblastic leukemia antigen (CALLA),[23] MB-1,[26] and OKT10.[22] Based on enzyme-linked immunosorbent assays, or immunoperoxidase and immunofluorescence evaluations under optimized conditions, MM4 does not react with normal BM cells or with peripheral blood normal T or B lymphocytes, granulocytes, or erythrocytes but binds to the majority of plasma cells in all plasma cell-derived cell lines and plasma cell dyscrasia BM biopsies tested.[21] In this study we examined whether this MoAb may be utilized as a means of selectivity eliminating myeloma cells in the presence of rabbit complement.

As a means of controlling for possible cell culture artifacts, the cytolytic properties of MM4 were examined with cells from three different plasma cell-derived cell lines. According

Table 2. Effect of MM4 + Complement Treatment on Cell Preparations Containing Normal Bone Marrow and Myeloma Cells

*GM 1312 cells were mixed with normal bone marrow mononuclear cells in the indicated ratios.

†Determined by stem cell colony-growth assay on day 7 and differentiated from marrow colonies by their distinctive colony morphology and irregular growth patttern. Value represents mean ± SD (n = 4).

‡Determined by short-term microcytotoxicity assay (see Materials and Methods). Mean ± SD (n = 3).

§CFU-C colonies were scored on day 10 and identified by their lack of color and relatively diffuse pattern. BFU-E were recognized by their red color and tightly packed colonies on day 14. Value represents mean ± SD (n = 4).

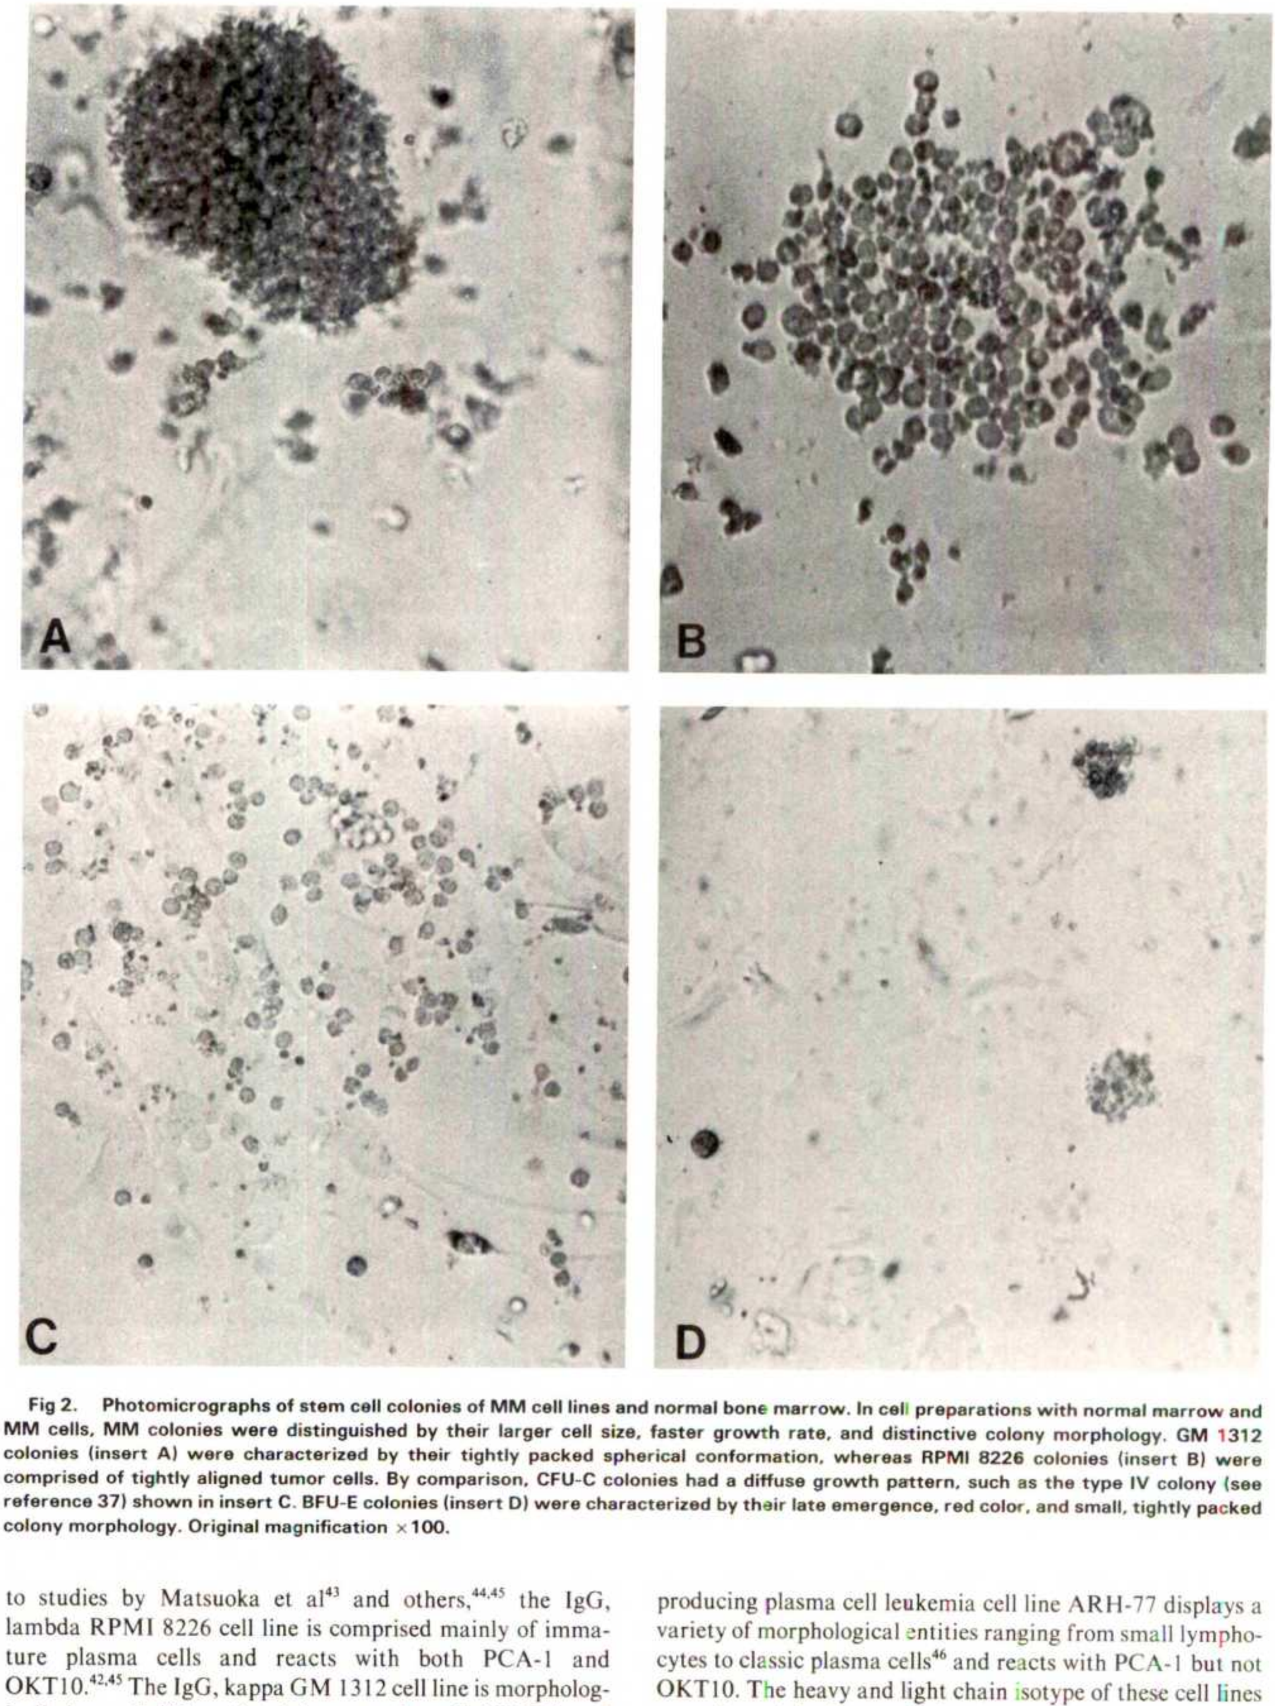

Fig 2. Photomicrographs of stem cell colonies of MM cell lines and normal bone marrow. In cell preparations with normal marrow and MM cells, MM colonies were distinguished by their larger cell size, faster growth rate, and distinctive colony morphology. GM 1312 colonies (insert A) were characterized by their tightly packed spherical conformation, whereas RPMI 8226 colonies (insert B) were comprised of tightly aligned tumor cells. By comparison, CFU-C colonies had a diffuse growth pattern, such as the type IV colony (see reference 37) shown in insert C. BFU-E colonies (insert D) were characterized by their late emergence, red color, and small, tightly packed colony morphology. Original magnification ×100.

to studies by Matsuoka et al[43] and others,[44,45] the IgG, lambda RPMI 8226 cell line is comprised mainly of immature plasma cells and reacts with both PCA-1 and OKT10.[42,45] The IgG, kappa GM 1312 cell line is morphologically less well differentiated, is unreactive with OKT10, and only weakly reactive with PCA-1.[44,45] The IgG kappa-producing plasma cell leukemia cell line ARH-77 displays a variety of morphological entities ranging from small lymphocytes to classic plasma cells[46] and reacts with PCA-1 but not OKT10. The heavy and light chain isotype of these cell lines as well as their immunologic phenotype were confirmed in this laboratory prior to and after culture under clonogenic

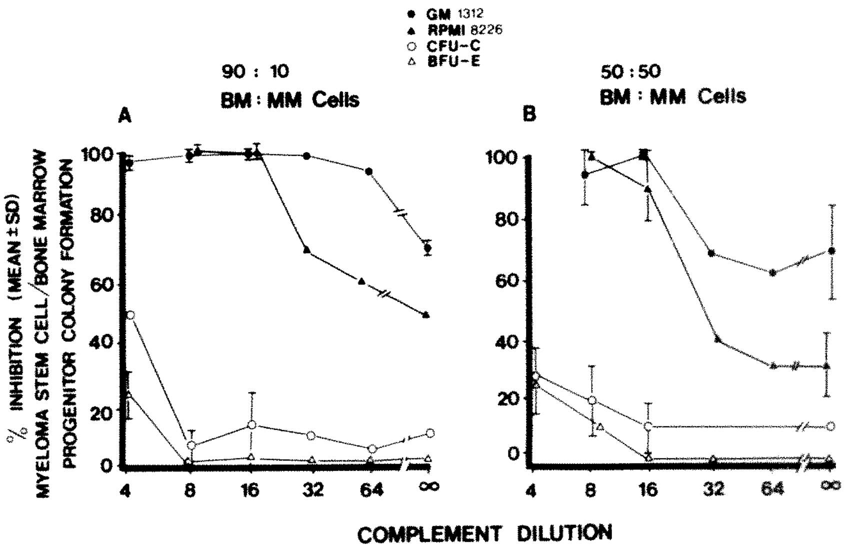

Fig 3. Eradication of myeloma stem cells in mixtures of myeloma and normal marrow cells by MM4 and complement. Normal bone marrow cells were mixed with cells from the MM cell line GM 1312 (●) or RPMI 8226 (▲) in proportions of 90:10 (A) and 50:50 (B). MM clonogenic stem cell colonies in MM4 + C′-treated or untreated samples were enumerated on day 7. Inhibition of normal bone marrow stem cell colonies CFU-C (○) and BFU-E (△) was determined on days 10 and 14, respectively. Value shown represents mean ± SD when based on three or more determinations. Effect of MM4 treatment without C′ is shown as complement dilution at ∞.

stem cell colony forming assay conditions. In this study it was evident that greater than 90% of cells from all three cell lines bound MM4, the majority of which were susceptible to complement-mediated cytolysis. The LD50s of 0.015 to 0.047 mg of MM4 per 10^5 cells were consistent with MoAb concentrations employed for cytolysis of other human tumors.[17-19] Parallel trypan blue exclusion studies indicated that MM4 + C′ was effective in killing >94% of total cells from the PCD cell lines tested.

More significantly, MM4 + C′ consistently abrogated clonogenic stem cell colony growth of the PCD cell lines tested, indicating that the clonogenic stem cell subset expressed the MM4-reactive antigen. As shown in this and our prior study,[27] MM4 alone was effective in inhibiting clonogenic stem cell colony formation of MM cell lines by an as yet undefined mechanism. The inhibitory effect was amplified by subsequent incubation with C′, and efficacy of clonogenic stem cell elimination was maintained in our experimental model of normal bone marrow cell preparations mixed with myeloma cells. MM4 + C′ eliminated 2 logs or more of clonogenic myeloma stem cells both in 90:10 and 50:50 preparations from RPMI 8226, GM 1312, or ARH-77 cell lines. The complement-inhibitory effect of BM cells, also documented previously by other investigators,[17,19] was evident in chromium release data but apparently did not affect the capacity of MM4 + C′ in deleting the clonogenic myeloma stem cell subset. Alternatively, this discrepancy may be related to assay artifacts, such as the resorption of released chromium from the lysed MM cells by normal bone marrow bystanders.

Table 3. Efficacy of MM4 + Complement in Eliminating Multiple Myeloma Clonogenic Stem Cell Colony Formation

	Clonogenic U/mL (Mean ± SD)†		
Cell Lines*	Prior Treatment (C_o)	After Treatment (C_t)	% Reduction‡
RPMI 8226	7.831 ± 3.681 × 10^3	45.47 ± 21.37	99.42
GM 1312	1.639 ± 0.770 × 10^3	18.19 ± 8.549	98.89
ARH-77	7.831 ± 3.681 × 10^3	2.512 ± 1.180	99.97
HS-Sultan	0.982 ± 0.452 × 10^3	1.915 ± 0.900	99.81

*Mixed with normal bone marrow mononuclear cells in the ratio of 90:10 (marrow:myeloma cells).

†Determined by limiting dilution and the Spearman estimate (see "Materials and Methods").

‡% Reduction = $(C_o - C_t)/C_o \times 100\%$.

In an earlier report[27] we found that approximately 70% of the total plasma cells in BM biopsies of MM patients express the MM4-reactive antigen. Our studies on established MM cell lines strongly suggest that the clonogenic stem cell subset from myeloma patients also expresses MM4. Whereas heterogeneity of antigen expression precludes the possibility of completely eradicating the entire myeloma/plasma cell population by MM4-mediated cytolysis, the same treatment can selectively eliminate the clonogenic stem cell subset. Several lines of evidence support the thesis that responsiveness of clonogenic stem cell cultures to cytotoxic or other agents correlate with in vivo therapeutic response.[39,47] In patients with multiple myeloma, Karp et al[48] and others[3,40] have shown that clonogenic colony-forming cells from MM marrow are closely related to kinetically active myeloma cells that proliferate in vivo. Elimination or major reduction of this stem cell subset may limit expansion of the myeloma cell clone with potentially advantageous therapeutic consequences.

Recent studies with leukemia and lymphoma cells have indicated success in purging malignant tumor cells from involved BM with the appropriate MoAbs, thereby providing the option for autologous marrow reconstitution following marrow-ablative chemoradiotherapy.[12-13,16] At present this therapeutic alternative is not available for patients with MM, despite syngeneic marrow transplantation studies suggesting that dose escalation may overcome apparent drug resistance in patients with refractory disease.[15] With the use of alkylating agent-predisone regimens, it is possible to achieve myeloma cell reduction to 10% or less of BM content in some MM patients.[1,8,9] Our experimental model suggests that it may be possible to further reduce the BM myeloma stem cell content by an additional 2 logs or more by incubating with MM4 + C′, thereby potentially achieving a total reduction of 3 logs or more of myeloma stem cells. Under the same experimental conditions, toxicity to CFU-C colonies ranged from 0% to 30%. Such experimental variability, which also has been reported by other investigators utilizing MoAb + C′ for purging of tumor cells,[49,50] may be attributable to background toxicity from C′ alone. Alternatively, we cannot exclude the possibility that the MM4-reactive antigen may be expressed on some normal BM progenitor cells at a low density level that ordinarily goes undetected. Immunofluorescence studies indicated that MM4 reacted weakly with a portion of normal BM cells (16.9% ± 9.2%) at a tenfold higher than usual incubating concentration, whereas reactivity with normal PBM cells remained negative (<1%) under such conditions. A proportion of these BM cells may be susceptible to C′-dependent lysis after exposure to MM4. In addition, MM4 is known to react with normal plasma cells,[27] which are present at low levels in normal marrow. Other studies also have demonstrated highly variable BM recovery (50% or less) in terms of cell number[49] or progenitor cell colonies[51,52] following purging procedures that involve MoAbs unreactive with normal BM. However, patient marrow reconstitution does not appear to be affected by such losses.[50,53] Our approach of myeloma cell depletion by MM4 + C′ thus remains potentially applicable for autologous marrow transplantation.

The results described in this paper deal with an experimental model for purging myeloma cells from bone marrow. The validity of this model has been supported by preliminary studies on BM from four MM patients, in whom we observed significant reduction in myeloma clonogenic stem cell colonies after treatment with MM4 + C′. These initial observations will be extended using BM from additional MM patients. Our data, as well as other studies employing complement,[16-19] indicate that the efficacy of selective tumor cytolysis is largely limited by activity and nonspecific toxicity of the complement source. MM4-immunotoxin conjugates may provide a more efficient mechanism for the elimination of myeloma cells in vitro.[20,54,55]

ACKNOWLEDGMENT

The authors express their appreciation to Susan Burkeholder and the staff of the Bone Marrow Transplantation Unit, Baylor University Medical Center, for their help in procuring bone marrow specimens, and to Sheryl Koleszar for assistance in the preparation of the manuscript.

Variability in 4-Hydroperoxycyclophosphamide Activity During Clinical Purging for Autologous Bone Marrow Transplantation

By Richard J. Jones, Michael Zuehlsdorf, Scott D. Rowley, John Hilton, George W. Santos,
Lyle L. Sensenbrenner, and O. Michael Colvin

We examined the effects of varying incubation conditions on the in vitro activity of 4-hydroperoxycyclophosphamide (4HC). 4HC activity against CFU-GM and against the K562 tumor cell line decreased with increasing the RBC concentration of the incubation mixture. Increasing the concentration of nucleated bone marrow cells in the incubation mixture also decreased the 4HC activity. Evaluation of 53 consecutive patients undergoing autologous bone marrow transplantation (BMT) revealed that the incubation RBC concentration during clinical purging showed a similar effect on CFU-GM recovery. Aldehyde dehydrogenase content of RBCs and nucleated marrow cells appears to be the cause of the inhibition of 4HC activity. Although there was no difference in individual CFU-GM sensitivity to 4HC among normals, previously treated patients undergoing autologous BMT showed significant variability in CFU-GM sensitivity to 4HC. The combined effects of incubation RBC concentration and individual patient 4HC sensitivity appear to account for most of the variability in CFU-GM recovery and speed of hematologic recovery after clinical purging with 4HC.

© 1987 by Grune & Stratton, Inc.

AUTOLOGOUS bone marrow transplantation (BMT) is a useful treatment for resistant acute leukemias, non-Hodgkin's lymphomas, and Hodgkin's disease.[1-6] However, a potential obstacle to the optimal utilization of this procedure is the contamination of the autologous graft with tumor cells, even when the tumor is absent morphologically. Sharkis and coworkers showed that 4HC could eliminate or purge leukemic cells from suspensions of marrow and tumor and still permit hematologic reconstitution.[7] Subsequently, purging with 4HC has undergone extensive preclinical and clinical study.[8-14] At our institution autologous marrow grafts are purged with 100 μg/mL of 4HC at a concentration of 2×10^7 nucleated marrow cells/mL for 30 minutes at 37°C. This dose of 4HC was the highest dose that permitted hematopoietic reconstitution in essentially all patients.[14] However, the time to hematopoietic recovery in these patients varied greatly.

Recently work from our institution showed that the CFU-GM content of 4HC-purged bone marrow grafts predicted the speed of hematopoietic recovery.[15,16] However, the recovery of CFU-GM following clinical 4HC-purging ranged from 0.07% to 23%.[15] The reasons for this 300-fold range in CFU-GM recovery are not all known but may represent differences in 4HC activity resulting from varied incubation conditions, differences in individual hematopoietic progenitor sensitivity, or a combination of both factors. Although serum concentration, nucleated cell concentration, time, and temperature of the 4HC incubation mixture were held constant during clinical purging, the RBC concentration of the incubation mixture varied considerably among patients. Preliminary clinical data from our institution suggested a relationship between the incubation RBC concentration and CFU-GM recovery following bone marrow purging with 4HC. A similar relationship for mafosfamide has also been suggested.[2]

To examine the possible causes of the variable CFU-GM recovery following clinical 4HC purging of autologous marrow grafts, we examined the effects of graded concentrations of RBCs and nucleated marrow cells on the in vitro activity of 4HC against normal human bone marrow and against the K562 myeloid leukemia cell line. We also studied the effects of the incubation RBC concentration during clinical purging with 4HC in 53 patients undergoing autologous bone marrow transplantation (BMT) for the treatment of malignancy. Individual CFU-GM sensitivity to 4HC was also determined for 21 patients receiving autologous transplants.

MATERIALS AND METHODS

Bone marrow cells. Bone marrow cells from healthy volunteers were obtained by aspiration from their posterior iliac crests. Samples of the bone marrow grafts harvested from 53 consecutive patients undergoing autologous bone marrow transplantation for the treatment of malignancy were obtained prior to and after clinical purging with 4HC. All healthy volunteers and patients gave informed consent for study participation as approved by The Johns Hopkins Joint Committee on Clinical Investigation. Mononuclear cells (density <1.078 g/mL) for CFU-GM assays were recovered by Ficoll-Hypaque (FH) density centrifugation.

4HC incubations. The 4HC (prepared by one of the authors, O.M. Colvin) was freshly dissolved prior to use. All clinical purging was performed as previously described.[3,14] Briefly, the nucleated cell buffy coat of the bone marrow graft was incubated with 100 μg/mL of 4HC in TC 199 medium containing 20% autologous plasma at a nucleated marrow cell concentration of 2×10^7 cells/mL for 30 minutes at 37°C. The incubation mixture was rapidly cooled to 4°C and centrifuged at 2900 rpm for ten minutes.

Bone marrow cells from normal donors or cells of the K562 myelogenous leukemia cell line[17] were incubated at concentrations of 5×10^6 cells/mL in enriched McCoy's 5A medium[18] with graded concentrations of 4HC at graded concentrations of autologous RBCs for 30 minutes at 37°C. To remove background red cells from the plates, red cells were lysed by incubating the mixture with 0.87%

NH_4Cl for ten minutes after washing the cells. Parallel experiments revealed that the NH_4Cl incubation did not alter the CFU-GM recovery. 4HC incubations with various concentrations of mononuclear bone marrow cells, K562 cells, and fetal bovine serum (FBS), and with individual patient serum replacing the FBS, were also performed.

Mononuclear bone marrow cells from 21 autologous bone marrow grafts, obtained prior to clinical purging with 4HC, and cells from 14 healthy volunteers were incubated with graded concentrations of 4HC at concentrations of 2×10^7 cells/mL for 30 minutes at 37°C to determine individual CFU-GM sensitivities to the drug in the absence of RBCs. All experimental 4HC incubations were arrested by the addition of chilled medium, and the cells were washed twice.

Colony assays. CFU-GM assays following the experimental incubations were performed using a modification of the technique described by Pike and Robinson.[18] 2×10^5 mononuclear bone marrow cells/mL were cultured in enriched McCoy's 5A medium containing 0.3% agar and 10% human placental-conditioned medium as a source of colony stimulating factor.[19] CFU-GM assays performed on the clinical autologous marrow grafts and those done on normal marrows to establish individual CFU-GM sensitivity to 4HC were performed as previously described.[20] Briefly, 5×10^4 to 1×10^6 mononuclear marrow cells/mL were cultured in 1.32% methylcellulose containing alpha medium, 5% phytohemagglutinin-stimulated leukocyte-conditioned medium, 1% bovine serum albumin (BSA), 30% fetal bovine serum (FBS), 10^{-6} mol/L methylprednisolone, 10^{-4} mol/L 2-mercaptoethanol, and 1 unit/mL erythropoietin. Clonogenic assays of K562 cells were performed using 0.3% agar, enriched McCoy's 5A medium, and between 200 and 10^4 cells/mL. Parallel experiments have shown that K562 colony growth is linear over this range, with inhibition of growth occurring at K562 cell densities greater than 10^4 cells/mL. One milliliter of the bone marrow or K562 cell mixture was plated in 35-mm petri dishes. The plates were incubated for ten to 14 days in a humidified atmosphere containing 5% CO_2 at 37°C. Assays were performed in quadruplicate, and the plates were scored using an inverted microscope. A colony was considered to be an aggregate of 40 or more cells.

Intracellular 4HC metabolism. Determination of intracellular metabolites of activated cyclophosphamide used 4HC prepared from [^{3}H-side chain] cyclophosphamide (Amersham) by the method of Hohorst et al.[21] Cells were exposed to the radiolabeled 4HC (20 μCi/μmole) at 37° before being rapidly separated from the radioactive medium by centrifuging through oil to give a cell pellet that is extracted by freeze-thawing at neutral pH. A protein-free extract was applied to a reverse phase C_{18} high-pressure liquid chromatography column and eluted with an ion-pairing solvent. Fractions of the eluate were collected and their radioactivity determined by scintillation counting. The intracellular concentration of individual components of the mixture of metabolites was determined from the specific activity of the [^{3}H] 4HC and the intracellular volume of the cells being analyzed.

Statistical evaluations. All the graphed data points from the preclinical studies were the means (±SEM) of two to four separate experiments performed in quadruplicate. The logarithms of percent surviving CFU-GM were plotted against the 4HC incubation concentration. Linear regression analyses (using results of individual experiments rather than means) with calculation of Pearson's correlation coefficients and significance levels were performed. The logarithms of surviving CFU-GM after incubation with 100 μg/mL 4HC were plotted against the respective 4HC incubation-packed RBC volumes for the clinical specimens. An exponential function, $y = be^{ax}$ (y = log of % surviving CFU-GM, x = incubation-packed RBC volume), was chosen as the best fit for the data. Linear regression analysis was employed to estimate the parameters a and b and to yield a correlation coefficient with significance level. The difference in the frequency of an increased CFU-GM sensitivity to 4HC between patients and normal donors was compared by the chi-square test.

RESULTS

The effect of RBC concentration on the activity of 4HC against CFU-GM from healthy donors was assessed. Graded concentrations of 4HC were incubated with 5×10^6 mononuclear marrow cells/mL for 30 minutes at 37°C at incubation-packed RBC volumes of 0%, 1%, 5%, 10%, and 20%. A significant linear relationship was found between the 4HC concentration and the logarithm of CFU-GM survival for each packed RBC volume tested (Fig 1). The 4HC activity against CFU-GM decreased with an increase in the RBC content of the incubation mixture. Similar effects of RBC on 4HC activity against K562 cells were observed (Fig 2). Again there was a significant linear relationship between 4HC concentration and the recovery of K562 clonogenic cells. Adding RBCs to the incubation mixture increased the survival of K562 cells.

The effect of varying the concentration of marrow mononuclear cells in the incubation mixture on 4HC activity was measured. Graded concentrations of 4HC were incubated with 5×10^6, 10×10^6, and 20×10^6 cells/mL for 30 minutes at 37°C. The CFU-GM survival (log) was significantly linearly related to the incubation dose of 4HC at each mononuclear cell concentration tested (Fig 3). The activity of 4HC also decreased with an increase in the concentration of mononuclear cells in the incubation mixture. Increasing

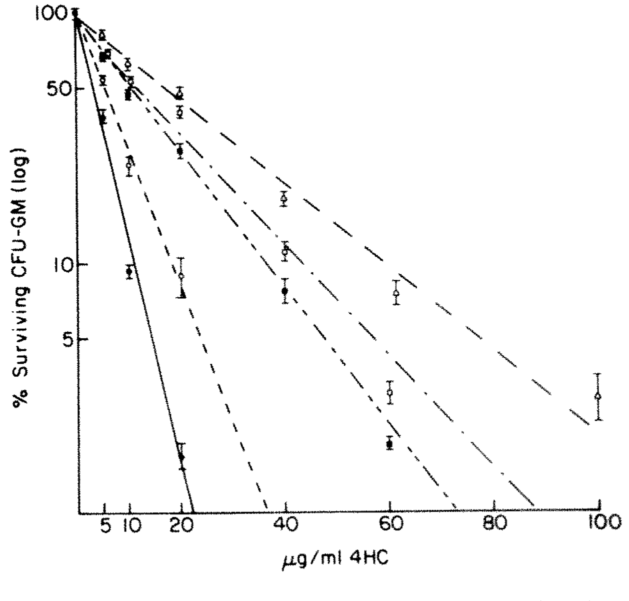

Fig 1. CFU-GM dose response to 4HC as a function of incubation hematocrit: ●——●, 0%; ○- -○, 1%; ■— - - —■, 5%; □— - —□, 10%; △— —△, 20%. The respective regression equations are: $y = 1.98 - 0.091x$ ($n = 46$, $r = -0.98$); $y = 1.99 - 0.057x$ ($n = 36$, $r = -0.95$); $y = 1.98 - 0.027x$ ($n = 52$, $r = -0.98$); $y = 1.94 - 0.022x$ ($n = 69$, $r = -0.94$); $y = 1.98 - 0.017x$ ($n = 62$, $r = -0.97$). All correlation coefficients are significant at $P < 10^{-6}$.

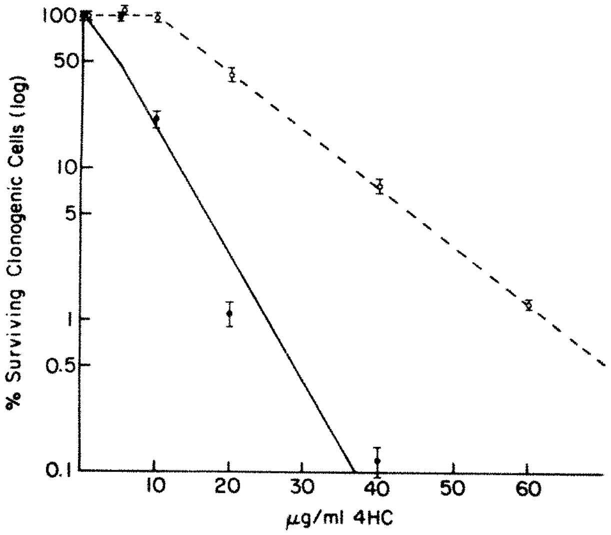

Fig 2. K562 dose response to 4HC as a function of incubation hematocrit; ●—●, 0% (y + 2 = 4.09 − 0.084 ×, n = 44, r = −0.94); ○ - - - ○, 10% (y + 2 = 4.36 − 0.38 × (n = 48, r = −0.98). Both correlation coefficients are significant at $P < 10^{-6}$. The initial shoulders were not included in the linear regression analyses.

the incubation concentration of K562 cells produced similar effects on the 4HC activity against these cells (data not shown).

Evaluation of the relationship between the RBC concentration of the incubation mixture during clinical purging with 4HC and CFU-GM recovery was performed in 53 consecutive patients undergoing autologous BMT. The incubation packed RBC volumes ranged from 4% to 23% with a mean of 8.7%. The CFU-GM recovery after 4HC treatment ranged from 0.01% to 23.8% (mean 1.4%). There was a statistically significant positive correlation between the incubation-packed RBC volume and CFU-GM recovery (Fig 4).

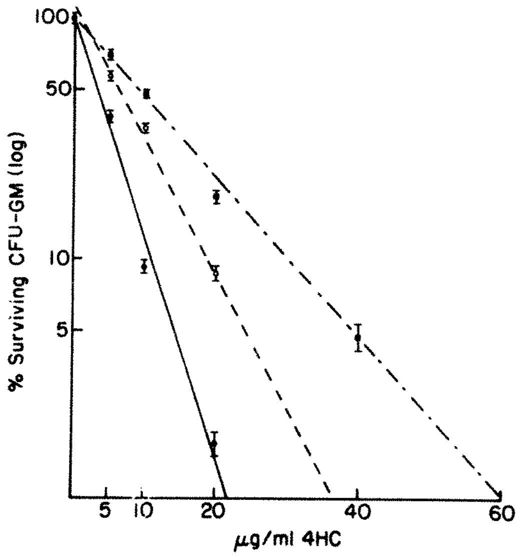

Fig 3. CFU-GM dose response to 4HC as a function of the incubation concentration of mononuclear bone marrow cells; ●—●, 5 × 10^6 cells/ml; ○ - - - ○, 10 × 10^6 cells/ml; ■ — - — ■, 20 × 10^6 cells/mL. The respective regression equations are: y = 1.98 − 0.091 × (n = 46, r = −0.98); y = 2.04 − 0.057 × (n = 40, r = −0.99); y = 2.0 − 0.034 × (n = 39, r = −0.98). All correlation coefficients are significant at $P < 10^{-6}$.

The individual CFU-GM sensitivity to 4HC was tested in 21 of the patients undergoing autologous BMT and 14 normal volunteers. Mononuclear bone marrow cells, obtained from autologous bone marrow grafts prior to clinical purging with 4HC, were incubated with graded concentrations of 4HC at cell concentrations of 2 × 10^7 cells/mL for 30 minutes at 37°C. The individual CFU-GM sensitivity to 4HC was expressed as the slope of the individual dose response obtained by plotting the concentration of 4HC (µg/mL) in the incubation mixture *v* the logarithm of the percent CFU-GM survival. The mean (±SD) 4HC sensitivity for the 14 normals was 0.03 ± 0.008. CFU-GM sensitivity to 4HC was greater than 1 SD above the mean in only one of 14 normal donors, while ten of 21 patients showed CFU-GM sensitivity to 4HC that was greater than 1 SD above the mean (P = .03). In addition, the CFU-GM sensitivity to 4HC was over 4 SD above the mean in two of these ten patients. No patient or normal donor had CFU-GM sensitivity to 4HC that was less than 1 SD below the mean. Differing concentrations of FBS or incubations with serum from different patients did not alter the 4HC sensitivities (data not shown).

The metabolism of 4HC in RBCs was followed by analysis of the intracellular concentrations of activated cyclophosphamide (4-hydroxycyclophosphamide), carboxyphosphamide, and phosphoramide mustard, which together make up 90% of the cyclophosphamide metabolites. Figure 5 indicates the concurrent disappearance of 4-hydroxycyclophosphamide and the appearance of carboxyphosphamide for 10^8 RBCs/mL. This model predicts that 10^8 RBCs/mL (or approximately a 1% incubation-packed RBC volume) would

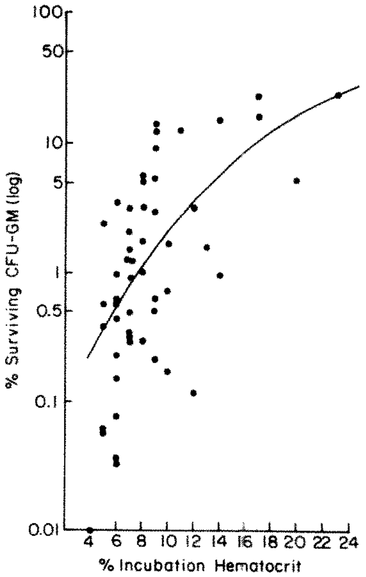

Fig 4. CFU-GM dose response to 4HC from patients undergoing autologous BMT based on incubation hematocrit. Regression equation is $2 - y = 3.54\,e^{-0.075x}$ (n = 53, r = 0.65, p < 0.01).

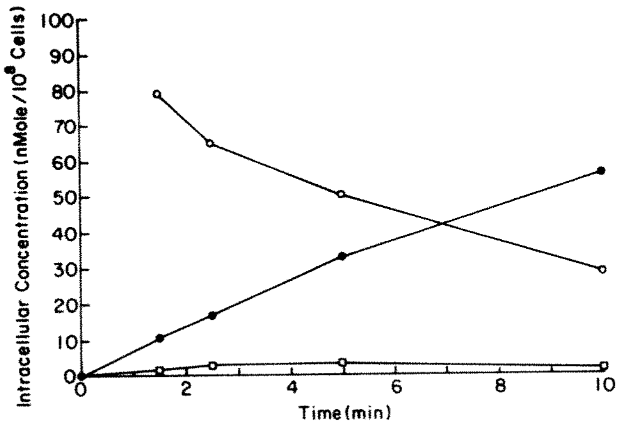

Fig 5. Analysis of cyclophosphamide metabolites in mouse RBCs; O—O, hydroxycyclophosphamide; ●—●, carboxyphosphamide; □—□, phosphoramide mustard. Mouse RBCs (10^8/mL) in RPMI 1640 medium were exposed to 100 μmol/L [^{3}H] 4-hydroperoxycyclophosphamide (20 μCi/μmol) at 37°C. One-milliliter samples were removed at the times indicated and the cells analyzed for cyclophosphamide metabolites as described in the "Methods" section.

metabolize approximately 5 nmol (1.5 μg) of 4HC to inactive carboxyphosphamide during each minute of incubation.

DISCUSSION

We found that variations in the concentration of RBCs or nucleated bone marrow cells in the incubation mixture during purging with 4HC will significantly alter the 4HC activity against CFU-GM. It appears that the actual 4HC effect associated with 100 μg/mL of 4HC incubated with 2×10^7 cells/mL and variable RBC concentrations ranges from that associated with 20 μg/mL to 80 μg/mL of 4HC in the absence of RBCs. This inhibitory effect of the RBCs on 4HC activity also exists toward tumor cells. Therefore a high incubation RBC concentration during clinical purging with 4HC would be expected to shorten hematologic recovery following autologous marrow transplantation but would also likely be associated with decreased tumor kill. Alternatively, a low incubation concentration of red cells should increase tumor kill but would significantly lengthen hematologic recovery. In addition, there is variation in CFU-GM sensitivity to 4HC among individual patients, as also occurs during purging with mafosfamide for autologous BMT.[2] Therefore the variable CFU-GM recoveries, and hence rates of hematologic recovery, seen after marrow purging with 4HC[3,15] result from variable concentrations of RBCs in the incubation mixture and individual patient differences in 4HC sensitivities.

It appears that the decreased 4HC activity seen with increasing the number of RBCs in the incubation mixture is due to the aldehyde dehydrogenase content of these cells. RBCs have been previously shown to contain measurable aldehyde dehydrogenase activity,[22] and the metabolism of 4HC in RBCs, as shown in Fig 5, is characteristic of a cell whose cyclophosphamide metabolism is dominated by aldehyde dehydrogenase.[23] The very rapid consumption of activated cyclophosphamide is consistent with the reduced in vitro activity of 4HC that occurs with increasing the RBC concentration. It is likely that the decreased activity of 4HC seen with increasing the number of mononuclear marrow cells or K562 cells in the incubation mixture is also due to aldehyde dehydrogenase activity in these cells. Bone marrow precursor cells[24] and K562 cells[25] have been shown to contain substantial amounts of this enzyme activity. It also has been shown that L1210 cells can develop resistance to cyclophosphamide through increased aldehyde dehydrogenase activity.[23]

Bone marrow progenitors from patients previously treated with chemotherapeutic agents are frequently more sensitive to 4HC than progenitors from normal donors. This effect of previous therapy on drug sensitivity is the opposite of what occurs with malignant tumors.[26] The reasons for the development of increased CFU-GM sensitivity to 4HC in previously treated patients undergoing autologous BMT are unknown. Radiation recall of normal tissues is another example of prior therapy causing normal tissues to become more sensitive to later chemotherapy.[27]

Two different culture conditions for CFU-GM assays were used in this study. The specimens from the studies shown in Figs 1 and 3 were assayed using standard conditions as described by Pike and Robinson.[18] The specimens from the autologous marrow grafts, and from normals used to determine individual patient CFU-GM sensitivity to 4HC, were assayed using an enriched methylcellulose culture system.[20] We found that the CFU-GM sensitivity to 4HC was not altered by the different culture conditions. The slope of dose response for 2×10^7 mononuclear bone marrow cells from normals incubated with 4HC for 30 minutes at 37°C was 0.03 using either the standard culture conditions (Fig 3) or the enriched methylcellulose culture system. We did find, however, that the enriched culture conditions allowed nearly a tenfold increase in CFU-GM cloning efficiency (data not shown).

It is important to standardize incubation conditions during clinical marrow purging. As we have shown, RBCs contaminating the incubation mixture for purging with 4HC are not inert. The mononuclear cell concentration, duration, and temperature of the incubation all affect the progenitor survival following treatment with 4HC. We have recently begun to adjust all incubation-packed red cell volumes to 7% during clinical purging with 4HC. This incubation RBC concentration was the value predicted by the regression line in Fig 4 for a CFU-GM recovery of 1.4%, the mean recovery seen in our study. Because of differences in CFU-GM sensitivity to mafosfamide between patients, Gorin et al[2] have suggested that the purging dose of this agent be individualized to ensure consistent engraftment. We have chosen, however, not to individualize the dosage of 4HC used in purging. We have found that just standardizing the RBC concentration of the incubation mixture prevents markedly prolonged granulocytopenia following autologous marrow transplantation. In addition, individualizing the dosage of a purging agent based on patient CFU-GM sensitivity does not take into account the potentially more important differences in individual tumor sensitivity to the purging agent.

A Specific Assay for Anti-HLA Antibodies: Application to Platelet Donor Selection

By Frederick E. Millard, Patricia Tani, and Robert McMillan

Alloimmunization to donor class I HLA antigens represents a major obstacle to successful platelet transfusion therapy. It is desirable to distinguish alloimmunization from nonimmunologic causes of poor platelet survival to assess the need for HLA-matched, single-donor platelets. We describe a new in vitro assay for anti-HLA antibodies and report its application to the problem of platelet crossmatching. In contrast to previously described crossmatch techniques, the immunobead assay is specific for anti-HLA antibodies. The assay was used to evaluate 51 single-donor platelet transfusions given to seven patients from 35 different donors. Recipient plasma was assayed for antibodies directed against HLA antigens present on donor platelets. A one-hour posttransfusion corrected count increment of ≥7,500 was considered a successful outcome. Twenty-nine of 33 (87.9%) transfusion episodes associated with a negative immunobead assay had successful outcomes. The four unsuccessful transfusions were associated with potential nonimmunologic causes of poor platelet survival. Only two of 18 (11.1%) episodes associated with a positive assay had successful outcomes. Only one unsuccessful transfusion episode was associated with a negative immunobead assay and a positive radiolabeled antiglobulin test result, which suggested that isolated alloantibodies to antigens other than class I HLA antigens are not a common cause of platelet refractoriness. Platelets stored in suspension at 4°C or frozen in liquid nitrogen were found suitable for crossmatch testing.

© *1987 by Grune & Stratton, Inc.*

SINCE ITS BEGINNINGS over three quarters of a century ago,[1] platelet transfusion therapy has played an increasingly important role in the supportive care of patients with bone marrow failure. A significant proportion of recipients become refractory to repeated transfusions from random donors due to alloantibodies to foreign class I HLA antigens present on the platelet surface.[2,3] Yankee et al first demonstrated that HLA-matched platelets from single donors frequently give good increments in this situation.[4,5] Unfortunately, HLA-matched donors are available for only a minority of alloimmunized patients, and the response to partially matched donors is less predictable.[6,7] The recognition of cross-reacting groups and the differential expression of certain HLA antigens (eg, B12) on platelets has facilitated educated guessing during donor selection[8-11]; however, a means of selecting appropriate donors without resorting to trial and error would be advantageous. A variety of approaches to platelet crossmatching have been investigated, but none has proved sufficiently convenient and reliable to become generally accepted.[12-23] In this report, we describe and characterize a new method of identifying anti-HLA alloantibodies. The method was used to evaluate 51 transfusion episodes in seven patients. A platelet radioactive antiglobulin test (RAGT) was performed simultaneously and the results compared with the immunobead results.

MATERIALS AND METHODS

Patient and Donor Population

Fifty-one transfusion episodes involving seven patients with bone marrow failure were studied (Table 1). All were refractory to random donor platelets before entry into the study. Transfusion episodes associated with fever, infection, or splenomegaly were not routinely excluded if good increments from any donor were seen within 24 hours. No patient demonstrated evidence of disseminated intravascular coagulation during the study period. Patient no. 1 was dropped from the study when he became refractory to all donors a few days before his death, associated with adult respiratory distress syndrome (ARDS) and mechanical ventilation. Patient no. 2 was dropped from the study when he became persistently febrile and refractory to all donors. He was subsequently determined to have a disseminated fungal infection. Donors were selected from family members when possible (n = 16), otherwise from paid community volunteers (n = 35). HLA matching was as follows: A, 9; B/B2X, 5; C, 19; D, 8; unknown, related, 7; unknown, unrelated, 3.[9]

Assessment of Transfusion Outcome

Each transfusion episode was evaluated by computing the one-hour corrected count increment (CCI) from the following standard formula: (one-hour postcount − pretransfusion count) × body surface area in square meters/number of platelets transfused/10^{11} = 1-hour CCI. When available, a later CCI (8 to 24 hours) was also calculated. A successful outcome was defined as a one-hour CCI of >7,500. In one instance, a one-hour CCI of 7,289 with a six-hour CCI of 4,252 was considered "successful" when a transfusion from an HLA-matched sibling given less than 24 hours later gave a one-hour CCI of 8,391 and six-hour CCI of 2,670. In two instances where one-hour platelet postcounts were not available, an eight-hour CCI <0 not associated with overt nonimmunologic causes of poor platelet survival was considered evidence of an unsuccessful transfusion outcome.

Murine Monoclonal Antibodies

HB-43 is an IgGκ antibody derived from the 1410K67 cell line, which recognizes the Fc portion of human IgG. HB-95 is an IgG2

antibody derived from the W6/32 cell line, which recognizes a monomorphic epitope on the heavy chain of human HLA-A, -B, and -C antigens.[24] The intact heterodimer is required for full expression of the epitope, although HB-95 binds weakly to isolated heavy chains.[25] Both cell lines were obtained from the American Type Culture Collection (Rockville, MD) and were used to produce ascites in Pristane-primed BALB/c mice from which antibody was purified by protein A affinity chromatography. ^{125}I labeling was accomplished by the chloramine-T procedure.[26]

Preparation and Storage of Platelets

Normal platelets. Blood from normal adult volunteers was drawn into EDTA and platelet-rich plasma separated by centrifugation at 400 g for ten minutes. The platelets were pelleted by centrifugation at 1,000 g for 15 minutes, washed four times with 1.0 mL of 0.05 mol/L citrate buffer (14.7 g sodium citrate, 5.9 g sodium chloride, and 25.0 g dextrose in 1,000 mL distilled H_2O, all of which was adjusted to pH 6.2 with 0.05 mol/L citric acid), and resuspended in citrate buffer to approximately 10^9/mL. Platelets were used fresh or stored in suspension at 4°C for 24 to 48 hours.

Donor platelets. Approximately 3 mL of platelet concentrate was obtained at the end of each pheresis procedure. This was divided into 1-mL aliquots and centrifuged at 750 g for 90 seconds to remove red cells. The platelets were centrifuged at 3,000 g for five minutes and washed four times. The platelet concentrate could be kept for 24 to 48 hours at 4°C before washing without affecting assay results.

Platelet storage. To assess the effect of storage on the immunobead assay, 1.0-mL platelet aliquots (1.3×10^9) from two normal donors were stored both in suspension at 4°C and by freezing in liquid nitrogen and then tested at intervals of 1, 6, 15, 30, 60, and 120 days against two control plasmas and two plasmas known to contain high-titer anti-HLA antibodies. Platelets to be frozen were suspended in autologous plasma with 5% dimethylsulfoxide in plastic tubes, frozen at −70°C overnight, then kept in liquid nitrogen. After thawing in a 37°C water bath, they were washed twice, resuspended in approximately 1 mL of citrate buffer, and counted. Parallel aliquots were suspended in normal saline with 0.02% sodium azide in plastic tubes and kept at 4°C. Before assay, the platelets were resuspended by pipetting, washed twice, and counted.

Preparation and Storage of Plasma and Serum

All assays were conducted on plasma, except as noted. Plasma was separated from EDTA-anticoagulated whole blood by centrifugation at 1,000 g for 15 minutes and kept in polypropylene tubes. Test plasma was obtained from recipients before transfusion and after any preceding transfusions whenever possible. In no case was test plasma obtained after the transfusion of interest. Positive control plasmas were obtained from multiply transfused individuals with known high-titer, broad-spectrum anti-HLA antibodies as demonstrated with the immunobead assay against a panel of normal platelets. Negative control plasmas were obtained from normal volunteers with no history of transfusion or pregnancy. Both positive and negative control plasmas were ultracentrifuged at 100,000 rpm for one hour. All plasmas were used fresh or stored frozen at −70°C. Repeated freezing and thawing was avoided.

Sera were prepared from a small number of positive and negative control plasmas by incubation in glass tubes in the presence of $CaCl_2$ and thrombin.

Immunobead Assay

The assay is depicted schematically in Fig 1. Aliquots of 10^8 donor platelets were sensitized by incubation with 100 mL of test or control plasma for one hour in plastic tubes. The sensitized platelets were washed three times, resuspended in 900 mL of citrate buffer, and solubilized by adding 100 mL of 10% Triton X-100. If the assay was to be completed the same day, the lysate was centrifuged at 3,000 g for five minutes and the supernatant transferred to 15-mL polypropylene tubes. The lysate could be frozen at −20°C after solubilization and the assay completed at a later date without affecting the results.

Immunobeads were prepared by incubating ¼-in polystyrene beads (#0023804, Pierce Chemical Co, Rockford, IL) with antihuman IgG (HB-43, 10 μg/bead) in 0.5 mL per bead of 0.01 mol/L $NaHCO_3$ buffer (pH 8.5) for one hour on a rotator. After four washes with 1.0 mL phosphate-buffered saline (PBS) Tween, they were incubated for an additional hour with 2% bovine serum albumin (1 mL/bead) to block residual binding sites. After four more washes, one bead was added to each tube containing platelet lysate and incubated with constant agitation for one hour. During this incubation, IgG alloantibodies that had been bound to the platelet before solubilization attach via the Fc portion to the HB-43 bound to the bead. The class I HLA antigen remains bound to the Fab portion of the alloantibody after solubilization and is thus bound indirectly to the bead. The beads were washed four more times in PBS-Tween, and incubated for one hour with 400,000 cpm of ^{125}I-labeled monoclonal anti-HLA antibody (HB-95) in 1 mL PBS-Tween. After four final washes, the beads were dried on a paper towel and counted in a Beckman gamma counter (Beckman Instruments, Inc, Fullerton, CA). All incubations were carried out at room temperature.

The test of interest was run in triplicate along with duplicates of one positive and two negative controls. One technician could run 24 simultaneous assays in approximately six hours.

RAGT

The RAGT was performed by a modification of the method of LoBuglio et al.[27] Briefly, 10^8 washed platelets were sensitized by incubation with 100 mL of plasma for one hour at room temperature and then washed three times in citrate buffer. A 3×10^7-aliquot was incubated for 30 minutes with 300,000 cpm of ^{125}I-labeled antihu-

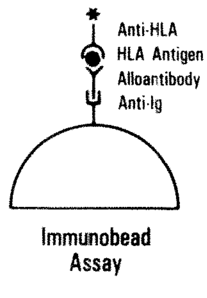

Fig 1. Schematic representation of the antigen-antibody "sandwich" that remains fixed to the polystyrene bead at the end of the assay. The anti-IgG is HB-43 and the anti-HLA, HB-95.

man IgG (HB-43). Triplicate 50-mL aliquots containing 6 × 10^6 platelets were layered over 200 mL of 30% sucrose in 400-μL plastic microcentrifuge tubes with tapered tips and centrifuged at 11,000 g for five minutes. After quick-freezing at −70°C, the tips containing the platelet button were removed and counted in a Beckman gamma counter.

Statistics

The overall predictive values of the immunobead and RAGT assays were compared with the binomial proportions test.

RESULTS

Characterization of the Immunobead Assay

Triplicate assays using 12 negative control plasmas against the same normal platelets gave a mean percent variation of 8.7% ± 9.0% (1 SD). Absolute values of negative controls generally fell in the range of 80 to 300 cpm. A single negative control plasma was also tested against the same platelets ten times and gave a mean percent variation of 6.3% ± 6.6%. Assays run using citrate buffer in place of plasma gave results comparable to negative controls.

To assess the possibility that the assay might recognize antiplatelet antibodies directed against non-HLA antigens, plasmas from 18 patients with the clinical syndrome of idiopathic thrombocytopenic purpura were tested against normal platelets. Seven of these had plasma autoantibodies to the glycoprotein (GP) IIb/IIIa complex, two had autoantibodies to glycoprotein Ib, and the remainder gave negative results for both these autoantibodies. Three plasmas gave positive results in the immunobead assay, two with GP IIb/IIIa autoantibodies and one with a strong antiplatelet autoantibody without demonstrable specificity. All three patients had a history of pregnancy and/or transfusion. Of the negatives, eight had a history of pregnancy or transfusion, two did not, and in five cases these data were not available.

Seven positive and seven negative controls were run with serum and compared with results using plasma. No significant difference was noted between negative controls. The absolute value of serum-positive controls averaged 60% of plasma values. No positives were missed by using serum.

Interpretation of Assay Results

The mean test result was divided by the mean of the negative controls to give a test/control ratio (TCR). Experiments with 12 normals gave a mean normal TCR of 1.00 ± 0.14 (1 SD). A TCR of <1.43 was initially defined as negative and included 3 SD. In practice, TCRs between 1.43 and 3.0 were associated with successful transfusion outcomes in five of six cases. This was interpreted as evidence that the immunobead assay can detect levels of alloantibody below that necessary to significantly affect platelet survival. That this was not due to random variation is supported by the observation that all nine A match transfusions were associated with TCRs <1.43. For clinical purposes, therefore, a TCR of ≤ 3.0 was considered negative and predictive of a successful transfusion outcome.

A TCR of ≤ 2.0 was empirically defined as negative for the RAGT by similar retrospective data analysis.

Correlation With Transfusion Outcome

Each evaluable transfusion episode was categorized according to whether the immunobead assay was positive (TCR, >3.0) or negative (TCR $\leq$ 3.0) and the outcome successful (one-hour CCI, $\geq 7{,}500$) or unsuccessful (one-hour CCI, $<7{,}500$). The data for both the immunobead assay and the RAGT are summarized in Table 2. The immunobead assay was positive in 18 episodes; 16 of 18 (88.9%) had unsuccessful outcomes. In 33 cases the assay was negative; 29 of 33 (87.9%) had successful outcomes. The mean one-hour CCI was 2,199 for assay-positive episodes and 13,072 for assay-negative episodes.

Twenty-one episodes were RAGT-positive; 15 of 21 (71.4%) had an unsuccessful outcome. Of the 30 RAGT-negative episodes, 25 of 30 (83.3%) had a successful outcome. The mean one-hour CCI was 3,897 for RAGT-positive episodes and 11,118 for RAGT-negative episodes.

Thus, the immunobead assay correctly predicted the outcome of 45 of 51 (88.2%) transfusion episodes, whereas the RAGT was correct in 40 of 51 (78.4%) episodes. The difference was not statistically significant ($P = .14$).

In a single instance (involving patient 1), a patient-donor combination initially associated with a positive immunobead assay and an unsuccessful outcome gave a negative assay and a successful outcome 1 month later. The initial transfusion was given just before preparation for bone marrow transplantation with high-dose cyclophosphamide and total nodal irradiation, which suggests that the alloantibody-producing lymphocytes were ablated, after which preformed antibody disappeared.

Figure 2 displays a plot of TCR *v* one-hour CCI that demonstrates the definition between positive and negative results.

Misclassified Transfusion Episodes

Of the six episodes misclassified by the immunobead assay, only one was correctly classified by the RAGT. Six of the 11 episodes misclassified by the RAGT were correctly classified by the immunobead assay. In five instances, both tests gave misleading results.

In the first immunobead assay–positive, successful outcome episode (patient no. 1), the TCR was 5.3 and the one-hour CCI, 16,897. The six-hour platelet postcount had fallen to below the pretransfusion level. The second case

Table 2. Correlation of Immunobead and RAGT Results With Transfusion Outcome

	Assay-Positive		Assay-Negative	
	CCI < 7,500	CCI > 7,500	CCI < 7,500	CCI > 7,500
Immunobead	16/18 (88.9%)	2/18 (11.1%)	4/33 (12.1%)	29/33 (87.9%)
RAGT	15/21 (71.4%)	6/21 (28.6%)	5/30 (16.7%)	25/30 (83.3%)

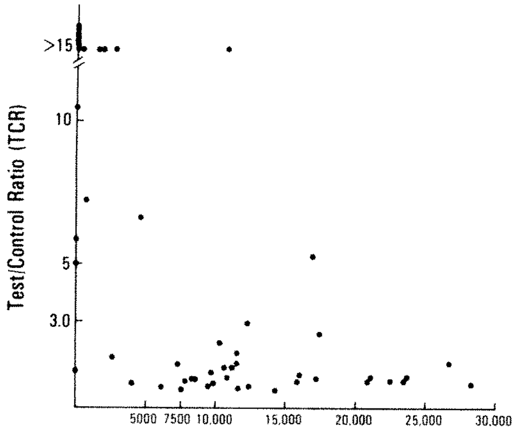

Fig 2. Plot of TCR *v* one-hour CCI for 51 transfusion episodes. A relatively sharp definition between positive and negative assays is seen.

(patient no. 6) had a TCR of 253.7 (the second highest recorded during the study), a one-hour CCI of 10,806, and a 16-hour CCI of 1,965. When the same donor was used again 4 weeks later, the TCR was 183 and the eight-hour CCI, 0. Both patients had unsuccessful outcomes with other donors associated with a positive immunobead assay.

The four assay-negative, unsuccessful outcome cases were all associated with potential non–alloantibody-related causes of poor platelet survival. The first (patient no. 2) was associated with fever and occurred five days before the patient became refractory to all donors and was dropped from the study (see the section Patient and Donor Population). The other three involved patient no. 1: the first occurred when platelets were given simultaneously with a granulocyte transfusion–associated febrile reaction, and the other two occurred after the patient had been intubated for ARDS but before he became refractory to all donors.

Feasibility of Using Stored Platelets

The mean positive control/negative control ratios for both platelet donors at each time interval are displayed in Table 3. The results indicate a significant deterioration in antigenic integrity or availability between one and six days, after which no further major deterioration was detectable through the longest interval tested (120 days). Platelets stored in suspension at 4°C maintained antigenic integrity slightly better than did the frozen platelets, although the difference was not marked. Although the positive controls used here remained markedly positive throughout the study, it is conceivable that plasmas with lower titers of anti-HLA antibody might become negative when tested against stored platelets. There was no significant loss of platelets due to storage during the study period.

Table 3. Immunobead Assay Results Using Platelets Stored Frozen in Liquid Nitrogen and in Suspension at 4°C

	Day of Storage					
Storage Method	1	6	15	30	60	120
Platelet donor no. 1

Liquid N_2	71.5	30.6	35.6	40.5	32.0	44.4

*Data are presented as mean positive control/negative control ratios.

DISCUSSION

The immunobead assay was originally developed to detect autoantibodies against platelet membrane glycoproteins.[28] We have adapted the assay to the study of alloantibodies to class I HLA antigens and applied it to the problem of platelet crossmatching. The results indicate the assay has sufficient predictive value to warrant wider-scale application.

The potential contributions of a reliable crossmatch technique to the conservation of blood bank resources and improved patient care are considerable. The incidence of alloimmunization in patients receiving repeated transfusions is estimated to be at least 50%, with only a small fraction having an HLA-matched related donor available.[29] One large center drawing on an HLA-typed pool of over 2,400 donors found an average of only 1.3 A-matched donors per patient, with 25% of patients having no A or B matches.[7] Most physicians treating alloimmunized patients have considerably smaller donor pools available. The use of partially mismatched platelets greatly enhances the usefulness of small donor pools but requires a reliable crossmatch technique for optimal utilization.

Ideally, prospective donors would have platelets stored when they enter the donor pool. When a patient with a poor response to random donor platelets is encountered, his or her plasma could be assayed against a small panel of normal platelets chosen to represent the common HLA antigens. If negative, it could be assumed that a problem other than alloimmunization against HLA antigens exists and the expense of single-donor platelets avoided. If positive, HLA-matched platelets would be indicated. In the majority of cases where these are not available, the best matches could be pulled from the donor pool and their stored platelets tested, selecting those who test negative. Although our storage study extended only 120 days, other studies suggest that much longer storage periods are feasible.[30-32]

One potential drawback to the immunobead assay is its HLA specificity. Many authors have suggested that alloantibodies to platelet-specific antigens account for some percentage of transfusion failures, usually based on poor response to HLA-identical platelets and/or the lack of demonstrable lymphocytotoxic antibody.[12,18-20,33-35] However, alloantibodies to platelet-specific antigens have been difficult to demonstrate conclusively in this setting, and their true significance remains uncertain. Herman et al used Western blots to study seven patients refractory to HLA-matched platelets and were unable to demonstrate antibody to platelet-specific antigen on the GP IIb/IIIa molecule.[36] They concluded that antibodies to platelet-specific antigens are not commonly present. Our finding of only one in 51 instances of poor transfusion outcome where the RAGT was positive and the immunobead assay negative tends to support this. It seems more likely that unrecognized nonimmunologic factors account for many if not all of these cases. However, it would seem prudent at present to use the RAGT or a similar non–HLA-specific assay to evaluate the presence of antibody to other platelet-associated antigens in cases where the HLA-specific immunobead assay is negative in the face of poor platelet survival.

ACKNOWLEDGMENT

We thank Dr George Dale for his valuable advice, the nurses and physicians of the Bone Marrow Transplant Unit for their assistance, and Drs William Miller, Michael Kosmo, and Gregory Marino for bringing appropriate patients to our attention.

T Cell Receptor (α, β, γ) Gene Rearrangements and Expression in Normal and Leukemic Large Granular Lymphocytes/Natural Killer Cells

By Pier-Giuseppe Pelicci, Paola Allavena, Milayna Subar, Alessandro Rambaldi, Anna Pirelli, Maria Di Bello, Tiziano Barbui, Daniel M. Knowles II, Riccardo Dalla-Favera, and Alberto Mantovani

The large granular lymphocyte (LGL) population, which effects a natural killer (NK) function, consists of cells whose lineage derivation has not been clearly established on the basis of phenotypic and functional properties. To clarify the relationship of LGL/NK cells to T cells we studied patterns of rearrangement and expression of the T cell receptor (Ti) genes α, β, and γ in normal human LGLs; in CD8$^+$, CD8$^-$, Mol$^+$, and Mol$^-$ LGL subsets; and in 17 cases of leukemic LGL proliferations (TγLPD). T_α, T_β, and T_γ genes were not expressed, nor were T_β and T_γ genes rearranged in normal LGLs or LGL subsets. The T_γLPD were divided into two groups. One group (15/17 cases) was characterized as CD3$^+$ and displayed Ti gene rearrangements. Seven of these cases were reactive with monoclonal antibody WT31, which suggested expression of an α/β heterodimer on the cell surface. The other group (2/17 cases) was CD3$^-$ with unrearranged Ti genes. These results indicate that the normal LGL/NK population is homogeneous and distinct from the normal T cell population because it does not express, and as a result, cannot effect its immune function through the T cell receptor molecules. Conversely, TγLPDs represent a heterogeneous group of lymphoproliferative diseases within which the CD3$^-$, Ti$^-$ cases most likely represent the neoplastic counterpart of normal LGL cells. The more frequent CD3$^+$ cases may be related to recently described NK-like T cells. The observations that normal LGLs maintain germline T_γ genes and that many CD3$^+$ TγLPD display an α/β heterodimer suggest that a T_γ-containing receptor may not be necessary for NK or NK-like cytotoxicity.

© 1987 by Grune & Stratton, Inc.

LARGE GRANULAR LYMPHOCYTES (LGL) are the principal effectors of natural killer (NK) function and antibody-dependent cell-mediated cytotoxicity (ADCC, K cell activity). They function in vivo as effectors of natural resistance against foreign cells, certain infectious agents, and tumor cells.[1,2] The LGL/NK population is heterogeneous and consists of cells sharing phenotypic and functional properties with both T cells and myelomonocytic cells.[1,2] As a result, their precise lineage derivation and mechanisms of immune function have remained unresolved and their place in hematopoietic differentiation pathways unclear.

The relationship of LGL development and function to the T cell lineage can be approached by analyzing T cell receptor gene rearrangements and expression. Two genes, T_α[3,4] and T_β[5,6] code for the complete T cell antigen receptor molecule in thymocytes and in peripheral blood T cells.[7] T_β gene rearrangements precede T_α gene rearrangements[3,8] and occur in all functional T cell subsets early during thymic differentiation.[9-11] A third gene, the T_γ gene, isolated from cytotoxic T cells is also a T cell–specific rearranging gene.[12,13] The T_γ gene is believed to rearrange even earlier in T cell differentiation, before the T_β gene.[14] Thus, T_β and T_γ gene rearrangements represent early and irreversible markers of the T cell lineage, whereas T_β and T_α gene expression correlates with expression of the T cell antigen receptor molecule.

Analyses of T cell receptor gene rearrangement and expression in various normal or neoplastic clonal LGL/NK populations derived from different species have led to a complex set of results that does not provide conclusions as to the lineage derivation or mechanisms of immune function of LGL/NK cells.[15-23] The majority of normal and neoplastic human NK clones[15,16] and all mouse NK clones[17,18] displayed T_β gene rearrangements and variably expressed T_β mRNA; a minority of human NK clones, both normal and neoplastic,[15,16] and all rat NK cell leukemias[19] displayed the germline configuration of the T_β gene and did not express T_β mRNA. Circulating LGL/NK cells freshly isolated from normal individuals display the germline configuration of the T_β and T_γ genes[20,21,23] and express a truncated version (1.0 kilobase [kb]) of the normal T_β mRNA (1.2 kb).[22] These discrepancies may reflect different criteria used for LGL/NK selection, the presence of heterogenous LGL/NK subpopulations, differences between normal and neoplastic LGL/NK cells, and finally, differences between different animal species. Based on these considerations, we comprehensively analyzed the genomic organization and patterns of expression of T cell receptor genes in normal and neoplastic human LGL/NK cells and in NK subpopulations selected according to their expression of T cell or myelomonocytic surface markers. We have extended previous studies on the T_β gene by including studies on T_α gene expression and on T_γ gene rearrangements and expression. Our data indicate that normal LGL/NK cells are ontogenically and functionally distinct from T cells.

MATERIALS AND METHODS

Isolation of Peripheral Blood LGLs, T Lymphocytes, and Thymocytes

Isolation of LGLs. Normal mononuclear cells were isolated by Ficoll-Hypaque density gradient centrifugation of fresh heparinized peripheral blood obtained from healthy donors. The peripheral blood

mononuclear cells were depleted of monocytes by plastic adherence and passage over a nylon wool column and were then fractioned on a six-step Percoll gradient ranging from 35% to 47.5%.[24] Cells from the low-density fractions (60% to 80% LGLs, 20×10^6 cell/mL) were collected and further depleted of mature T cells by repeated 30-minute incubations with monoclonal antibody (MoAb) OKT3 (diluted 1:100; gift of Dr E. Reinherz, Boston) or MoAb Leu-l (Becton Dickinson, Mountain View, CA) and 60-minute incubations with complement (diluted 1:4, Pel-Freeze Laboratories, Rogers, AR). The purity of each LGL preparation was assessed by morphology, the expression of MoAb-defined cell surface antigens, and in vitro cytotoxic activity (see Table 1). Purified fractions of phenotypically distinct LGL/NK subpopulations were then obtained by column immunoabsorption or cell sorting[25] using MoAbs OKT8 and Mol, which identify phenotypically[26,27] and functionally[28,29] distinct LGL/NK subsets. MoAb OKT8 recognizes the CD8 antigen, which is present on the mature T cell subset commonly associated with suppressor/cytotoxic function[30] and on approximately 30% of LGLs (Table 1).[26] MoAb Mol reacts with the Mol epitope of the C3bi receptor,[31] which is present on monocytes, myeloid cells,[32] and approximately 70% of LGLs (Table 1).[26,27,32]

T lymphocytes. Peripheral blood T lymphocytes were isolated by fractionation of peripheral blood mononuclear cells on a Ficoll-Hypaque density gradient according to their capacity to form E rosettes with *Vibrio cholerae* neuraminidase–treated sheep erythrocytes.[33] The E$^+$ fraction consisted of >95% T cells as determined by CD3 expression. The E$^+$ fraction was incubated with OKT8 and OKT4 MoAbs and complement at 37°C to obtain purified fractions of CD4$^+$ and CD8$^+$ cells, respectively. The resulting cell populations were 95% pure as determined by CD4 and CD8 expression.

Thymocytes. Thymocytes were isolated from portions of thymuses collected during the course of cardiac surgery.

MoAb-defined cell surface markers and morphology. The surface immunophenotype of the isolated cells was determined by indirect immunofluorescence using a Zeiss microscope and/or a FACS IV (Becton Dickinson). The following panel of MoAbs was used: OKT3, OKT6, OKT8, OKT11 (Ortho Diagnostic Systems, Inc, Raritan, NJ, or the gift of Dr Reinherz, Dana-Farber Cancer Institute, Boston); HNK-1 (courtesy of Dr Abo, Birmingham, AL), which is reactive with NK cells and a subset of T cells[34]; B73.1 (courtesy of Dr G. Trinchieri, Philadelphia)[2] and AB8.28 (courtesy of Dr Malavasi, Turin, Italy)[35] both reactive with a structure closely associated with the Fc$_\gamma$ receptor of LGLs; N901, reactive with LGLs and some myeloid precursors (courtesy of Dr J. Griffin, Boston),[36] WT31, reactive with a common epitope of the T cell receptor α/β heterodimer (courtesy of Dr W.J.N. Tax, Amsterdam[37]), Leu-11, reactive with the CD16 antigen; and Leu-7 (Becton Dickinson Monoclonal Center, Inc, Mountain View, CA).

Table 1. Phenotypic and Functional Analysis of LGLs and LGL Subpopulations

	Phenotypic Markers*					Cytotoxicity†	
LGL Population	CD8	CD3	Mo1	HNK1	N901	NK	ADCC

T lymphocytes	45	98	0	0	ND	2	1

Abbreviation: ND, not done.

*Numbers represent the percentage of positive cells for each of the MoAb stainings.

†Results are expressed as means and refer to an E:T ratio of 50:1.

Cytotoxicity assays. NK activity was assessed by using the K562 cell line at effector-to-target cell (E:T) ratios ranging from 25:1 to 100:1 in a four-hour in a ^{51}Cr release assay as previously described.[38] For ADCC, ^{51}Cr-labeled TLX9 murine lymphoma cells sensitized with 1:10,000 rabbit antibody were used as targets in a four-hour test.

DNA extraction and Southern blot analysis. DNA was prepared by cell lysis, proteinase K digestion, extraction with phenol, and precipitation with ethanol.[39] Fifteen micrograms of DNA were digested with the appropriate restriction endonuclease, electrophoresed in a 0.8% agarose gel, denatured, neutralized, transferred to a nitrocellulose filter, and hybridized and washed according to Southern.[39] Hybridized filters were boiled for five minutes in distilled H_2O before hybridization to a second DNA probe.

RNA extraction and Northern blot analysis. Total cellular RNA was extracted according to the guanidine-isothiocyanate method.[39] Five to 10 μg of purified total RNA were electrophoresed in a 1% formaldehyde–containing agarose gel, transferred to nitrocellulose, hybridized, and washed according to established procedures.[39]

DNA Probes

T_β probe. The T_β probe used in this study was derived from a human T_β cDNA clone (YTJ-2) isolated from the Jurkat-2 T lymphoma cell line (courtesy of Dr Tak Mak).[5] This clone hybridizes to both alleles ($C_{\beta 1}$ and $C_{\beta 2}$) of the constant region and to one or more alleles of the variable regions.[5,40]

T_γ probes. Three different T_γ probes were used in this study. The Ca/Cb and V2 probes were derived from two human T_γ cDNAs. The $F_\gamma 7$ cDNA isolated from the Fro 2.2 T lymphoma cell line represents an aberrantly rearranged T_γ allele.[57] The V2 probe is representative of the variable region of $F_\gamma 7$ cDNA and belongs to the $V_\gamma I$ variable region family.[41] The $T_\gamma 5$ cDNA isolated from a peripheral T cell library represents a truncated T_γ constant region. The Ca/Cb probe represents the first exon of $T_\gamma 5$ cDNA (M. Subar et al, submitted for publication). The pJx2 probe is a genomic probe derived from the G2.0 T_γ genomic phage isolated from a Charon 4A human placental library. It represents a unique *Eco*RI-*Hind*III fragment containing the putative J region of the $F_\gamma 7$ cDNA clone.[57] The positions of these three probes with respect to the $F_\gamma 7$ and $T_\gamma 5$ cDNA clones and the human T_γ gene are schematically represented in Fig 1. DNA fragments were ^{32}P labeled by nick-translation[39] for use as probes.

RESULTS

Analysis of T Cell Receptor (α,β) Gene Rearrangements and Expression in LGL/NK Cells and Subsets

Freshly isolated peripheral blood LGLs display the germline organization of the T_β gene but express a truncated version of T_β mRNA.[20-22] However, the majority of clonal LGL/NK cell populations display T_β gene rearrangements.[15-19] Because T cells invariably display T_β gene rearrangements and expression, these data do not permit an unequivocal understanding of the relationship between LGL/NK cells and T cells. To clarify this issue, we tested the hypothesis that minor LGL/NK subpopulations may display T cell receptor gene rearrangements. This hypothesis is particularly relevant in view of the fact that (*a*) a minor LGL/NK subpopulation (30%, see Table 1) is identifiable by the expression of the T cell–specific CD8 antigen and (*b*) a minor LGL/NK subpopulation carrying T_β gene rear-

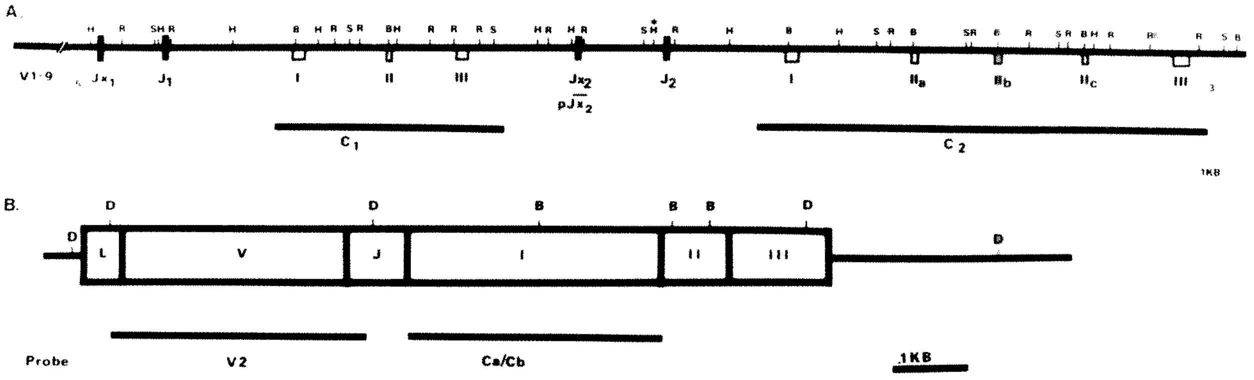

Fig 1. Restriction enzyme maps of the human T_γ locus and of the $F_\gamma 7$ human T_γ cDNA. (A) The two genes (C1, C2) that compose the T_γ constant region locus are indicated. Exons I, II a to c, and III are labeled and indicated by boxes. The pJx2 probe is as shown. (B) The leader (L), variable (V), joining (J) and three constant region exons (CI, CII, CIII) that compose $F_\gamma 7$ cDNA are indicated. The bar below the map indicates a probe representative of the $F_\gamma 7$ variable region (V2). The area equivalent to the Ca/Cb probe derived from the first exon of the $T_\gamma 5$ cDNA is indicated.

rangements could escape analysis when the total LGL/NK population was examined. For these reasons, we analyzed the organization and expression of T cell receptor α and β genes in phenotypically distinct LGL/NK cell subpopulations as well as in unfractionated normal LGL/NK cells.

The genomic organization of the T_β gene was investigated by Southern blot hybridization using a DNA probe specific for the human T_β gene locus. We had previously shown that hybridization of this probe to *Eco*RI-digested DNAs allows the detection of T_β gene rearrangements in both monoclonal and polyclonal T cell populations.[40] The biallelic rearrangement of part of the constant region ($T_\beta C$) can be recognized as a loss of the 12.0-kb *Eco*RI band corresponding to the $C_{\beta 1}$ region in normal, polyclonal human thymocytes and T lymphocytes[40] (see Fig 2, lane T-L). When the total LGL/NK population was studied in this manner, the T_β gene was found in its unrearranged germline configuration. Identical results were obtained in purified $CD8^+$ and $Mo1^+$ LGL/NK subpopulations (Fig 2). In the experiment shown in Fig 2, LGLs were pretreated with anti-CD3 to remove possible conventional T-cell contaminants, but similar results were obtained with anti-Leu-1 (CD5)-treated cells or with the untreated Percoll-purified population. Comparative densitometric analysis of the *Eco*RI 12.0-kb band *v* the other bands in LGL/NK and control cells confirmed that there is no appreciable loss of the $C_{\beta 1}$ allele in the different LGL/NK populations analyzed (data not shown). Therefore, we conclude that the T_β gene remains unrearranged in the vast majority of normal LGL/NK cells.

We next investigated T_α gene expression in freshly isolated LGL/NK cells because a molecular assay to detect T_α gene rearrangements in normal polyclonal cells is not yet available. RNA was extracted from purified LGLs and from the CD8+ LGL/NK subpopulation and analyzed by Northern blot hybridization using a T_α probe (clone PY1.4, a gift from T. Mak). T_α RNA was not detectable in either sample (see Fig 3, middle lane). The same RNA blots were used for hybridization with a human T_β probe (Fig 3, first lane), and no specific hybridization signal was detected. The absence of the CD3 antigen and T_β and T_α gene expression in LGL/NK cells proves that LGL/NK cells do not express an α/β heterodimer on their surface.

Analysis of T_γ Gene Rearrangements and Expression in Normal LGLs, LGL Subpopulations, and T Cells

The lack of T_β gene rearrangements and T_β/T_α gene expression in the majority of LGL/NK cells suggests that the "conventional" T cell antigen receptor is not involved in NK target cell interaction. However, the ontogenic relationship between LGL/NK cells and T cells remains unresolved because T_β and T_α genes are neither rearranged nor expressed in early thymocytes[11] and both early thymocytes

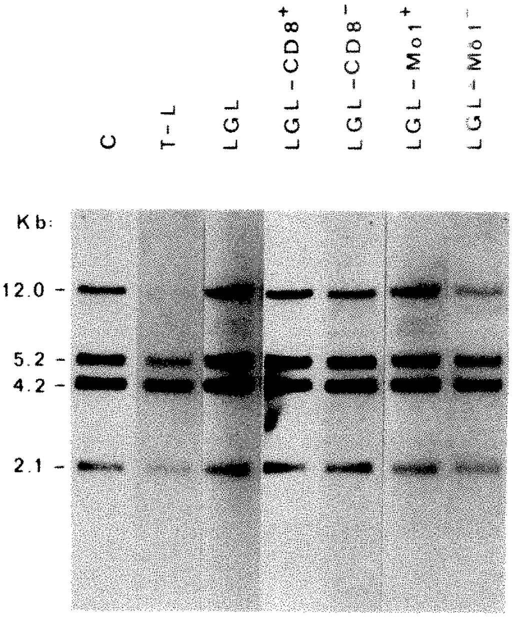

Fig 2. T_β gene rearrangement analysis in fresh uncultured LGLs and LGL subpopulations. DNAs extracted from normal human fibroblasts (lane C), normal human peripheral blood T lymphocytes (lane T-L), and different LGL subpopulations, as indicated, were digested with *Eco*RI restriction enzyme and analyzed by Southern blot hybridization using a T_β gene probe.

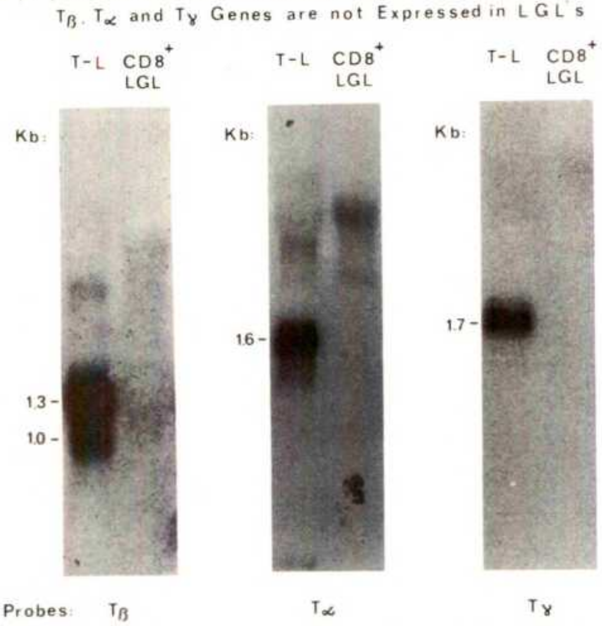

Fig 3. Expression of T_β, T_α, and T_γ RNA in CD8$^+$ LGLs and peripheral blood T lymphocytes. Total cellular RNA was extracted from the CD8$^+$ LGL subpopulation and peripheral blood T lymphocytes (T-L). Northern blots were hybridized to T_β, T_α, and T_γ probes as indicated.

and the majority of LGL/NK cells lack CD3 antigen expression and express the CD8 antigen.[2] We then chose to analyze LGL/NK cells for rearrangement and expression of a third T cell receptor gene, the T_γ gene, which is believed to rearrange early during T cell differentiation before the T_β and T_α genes[14] and may therefore represent a marker for the earliest stages of the thymic differentiation pathway. The T_γ gene has been reported to remain in its germline organization in the total LGL/NK population.[23] However, this analysis was limited to the investigation of T_γ gene rearrangements involving the $T_\gamma J1$ or $T_\gamma J2$ regions. We have recently shown that T_γ rearrangements involving previously unidentified $T_\gamma J$ regions (Jx2; M. Subar et al, submitted for publication) may occur in 25% of T cells and up to 30% of pre-B cells.

Our experimental approach involved Southern blot hybridization analysis of T_γ gene organization in DNAs extracted from the total LGL/NK cell population as well as the CD8$^+$ and CD8$^-$ LGL/NK subpopulations. The results were compared with Southern blot analyses of the T_γ gene organization in DNAs extracted from normal polyclonal T cell populations. The assay for identification of different patterns of T_γ gene rearrangements was based upon results of the analysis of T_γ gene rearrangements in a large variety of clonal T cell populations (M. Subar et al, submitted for publication). A diminution in the intensity of the 5.5-kb *Eco*RI band hybridizing to a T_γ first-exon probe (Ca/Cb) in all polyclonal T cells (see Fig 4A) corresponds to deletions of the $T_\gamma C1$ locus, which are constantly associated with rearrangements of the $T_\gamma C2$ locus (M. Subar et al, submitted for publication). The appearance of a 7.5-kb *Sst*I band hybridizing to the T_γ variable region probe (see Fig 4B) reflects rearrangements involving a member of this variable region family and is seen in polyclonal T cells as in the majority of clonal T cell populations (M. Subar et al, submitted for publication). The appearance of a few faintly hybridizing, Jx2-rearranged bands corresponds to $T_\gamma C1$ rearrangements (see Fig 4C).

The T_γ gene was present in its germline configuration in all DNAs extracted from polyclonal LGL/NK cells and the CD8$^+$ and CD8$^-$ LGL/NK subpopulations. Representative Southern blots for the CD8$^+$ and CD8$^-$ LGL/NK DNAs are shown in Fig 4. We also analyzed the expression of the T_γ gene in the total LGL/NK population and in LGL/NK subsets. No specific hybridization signal was detected in any of the samples (for representative results, see Fig 3, right lane). We conclude that LGL/NK cells and CD8$^+$ and CD8$^-$ LGL/NK cell subpopulations are clearly distinct from both mature and immature T cells with respect to the organization of the T_γ gene and that the T_γ gene is not rearranged or expressed in the majority of, if not all, LGL/NK cells.

Gene Rearrangements and Expression Analysis of T Cell Receptor Genes in Human LGL/NK-Derived Leukemias

An approach commonly used to investigate properties of a normal cell population is to analyze its clonally expanded neoplastic counterpart. This is based on the concept that malignant transformation results in freezing the target cell at a given stage in its normal differentiation pathway, which

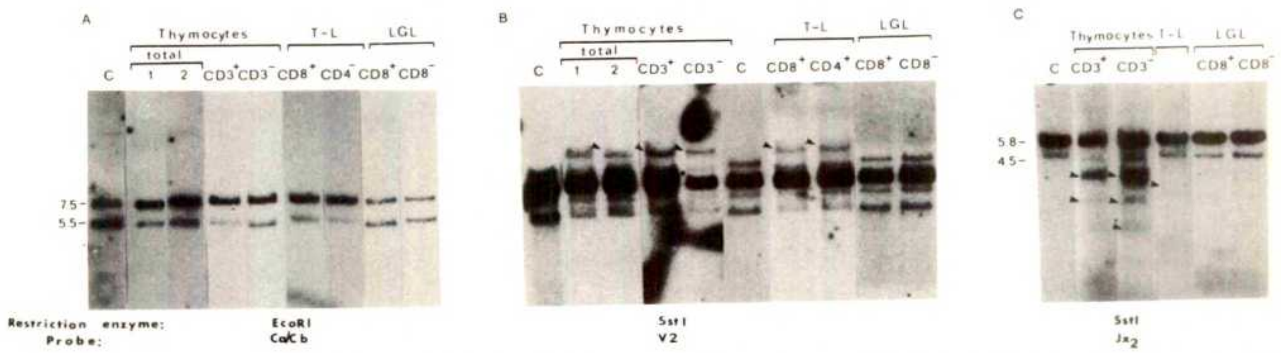

Fig 4. T_γ gene rearrangement analysis in normal T cells and LGLs. DNAs were extracted from different cell populations, digested with the indicated restriction enzymes, and hybridized to the indicated T_γ DNA probes. Arrows indicate rearranged bands. Lane C, human fibroblast DNA.

results in a uniform phenotype for the neoplastic cell population. For this reason, we analyzed the genomic organization of the T cell receptor genes β and γ in a collection of 17 LGL leukemias, so-called Tγ lymphoproliferative disorders (TγLPD).[42]

The principal immunophenotypic, functional, and immunogenotypic properties of 12 of these 17 cases of TγLPD have been reported in detail.[16] The five additional cases of TγLPD shown in this study displayed similar phenotypic and functional features including CD2, HNK-1, AB8.28, and B73.1 expression; Fc_γ receptors identified by rosetting technique; and ADCC effector function (data not shown). Surface markers CD3, CD8, OKM1, and N901 were detected in the LGLs isolated from some but not all cases (data not shown). In particular, two cases did not express the CD3 antigen (Table 2). LGLs from all TγLPD patients had high ADCC, whereas high NK activity was only detected in six cases (Table 3).[16] Fifteen cases displayed clonal rearrangements of the T_β gene, and two cases displayed the germline configuration of the T_β gene upon *Eco*RI and/or *Bam*HI digestion and hybridization to a T_β probe (data not shown). The two cases displaying the T_β gene germline organization were the same two cases that lacked the CD3 antigen.

All 17 cases of TγLPD were analyzed for the organization of the T_γ gene. Representative Southern blots of this analysis are shown in Fig 5, and a synthesis of the results is reported in Table 2. We detected T_γ gene rearrangements in 15 of 17 TγLPD cases tested using the same combination of restriction enzymes and probes described for the analysis of T_γ gene

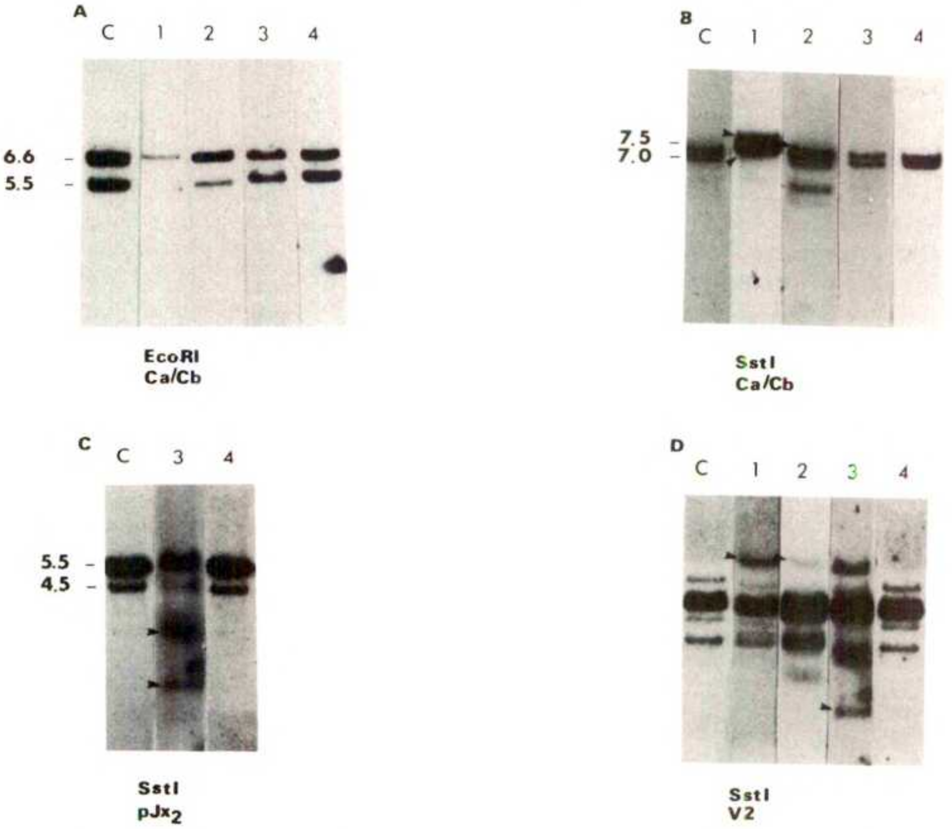

Fig 5. T_γ gene rearrangement analysis of T_γLPDs. DNAs were extracted from leukemic LGLs of different TγLPD patients, digested with the indicated restriction enzyme, and hybridized to the indicated probe. Arrows indicate rearranged bands. Lane C, human fibroblast DNA.

rearrangements in polyclonal T cells. In 12 of 17 TγLPD DNAs tested, the Ca/Cb hybridizing 5.5-kb *Eco*RI band corresponding to exon I of the $T_{\gamma}C1$ gene appeared deleted or fainter than the respective control bands, which suggested a deletion of that DNA region on one or both alleles (see Fig 5A, lanes 1 and 2, for representative results displaying the biallelic or monoallelic deletion of the $T_{\gamma}C1$ gene, respectively). The same DNAs were digested with the *Sst*I restriction enzyme and hybridized to the Ca/Cb probe to detect rearrangements involving the J1 or J2 regions (for a map of the T_{γ} locus, see Fig 1A). One or two rearranged bands were detected in each of these 12 cases (see Fig 5B, lanes 1 and 2). Hybridization of the same blots to a T_{γ} variable region probe (V2) showed the appearance of one or two rearranged bands (Fig 5D, lanes 1 and 2) with at least one rearranged band containing both V2 and Ca/Cb hybridizing sequences as indicated by arrows in Fig 5B and D. We conclude that 12 TγLPD cases displayed rearrangements occurring in the $T_{\gamma}C2$ 5′ flanking sequences involving the J2 region and T_{γ} variable region sequences.

The 5.5-kb *Eco*RI band hybridizing to the Ca/Cb probe showed equal intensity with the control bands in five other cases of TγLPD, which suggested that the $T_{\gamma}C1$ locus was not deleted (see Fig 5, lane 3). Hybridization of *Sst*I-digested DNAs to a Jx2 probe can detect rearrangements in the 5′ flanking regions of the $T_{\gamma}C1$ locus. New *Sst*I restriction fragments hybridizing to the pJx2 probe were detected in three TγLPD cases, which suggested the occurrence of $T_{\gamma}C1$ gene rearrangements (Fig 5C, lane 3). Hybridization of the same blots to a T_{γ} variable region probe (V2) showed that the new bands also contained variable region sequences as indicated by arrows in Fig 5C and D. Finally, in two cases (Table 2), the T_{γ} gene was found in its germline configuration using all of the combinations of restriction enzymes and probes described (see Fig 5A, B, C, and D, lane 4 for a representative case). As in the case of the T_{β} gene, these two cases also lacked the CD3 antigen (Table 2). We conclude that the T_{γ} gene is rearranged in all $CD3^{+}$ cases of TγLPD but it is retained in its germline configuration in the less frequently occurring $CD3^{-}$ cases of TγLPD. In addition, T_{γ} gene rearrangements using $T_{\gamma}C1$ or $T_{\gamma}C2$ are present in $CD3^{+}$ TγLPD cases in similar proportions to those observed in T cell tumors.

Two and one representative cases of $CD3^{+}$ and $CD3^{-}$ TγLPD respectively were also analyzed for T cell receptor gene expression. The two $CD3^{+}$ TγLPD cases displayed expression of full-length mRNAs from T_{β}, T_{α}, and T_{γ}, whereas the $CD3^{-}$ TγLPD case displayed no hybridization signal for all the T cell receptor gene probes (data not shown).

In an effort to elucidate whether the $CD3^{+}$ TγLPD with rearranged and expressed T cell receptor genes produces a "conventional" cell surface α/β heterodimer or the recently described T_{γ}-containing T cell receptor,[43-47] we investigated seven cases of $CD3^{+}$ TγLPD with MoAb WT31, which reacts with a common epitope of the α/β heterodimer but not with T_{α}^{-}, T_{β}^{-}, T_{γ}^{+} cells.[37,43-47] In preliminary experiments we confirmed that $CD3^{+}$, $CD8^{-}$, $CD4^{-}$ clones were $WT31^{-}$.[43-47] As summarized in Table 3, all seven cases were $WT31^{+}$. In case 15, in spite of the monoclonal nature of the $CD3^{+}$ expansion revealed by Southern blot analysis (see earlier), a fraction of $CD3^{+}$ cells were not appreciably stained by the WT31 MoAb. It is of interest in this context that all TγLPD cases were $CD8^{+}$ (as usually observed)[16,42] and that T cell clones expressing a T_{γ}-containing receptor are CD8−, CD4−.[43-45] Thus, the observation of WT31 reactivity together with the finding of T_{α} and T_{β} mRNA and CD8 expression suggests that the majority of TγLPD express a "conventional" α/β heterodimer on their surface.

DISCUSSION

LGL/NK cells constitute a heterogeneous population that cannot be clearly assigned to a specific lymphoid lineage. We sought to clarify the functional and ontogenic relationship between LGL/NK cells and T cells by analyzing the organization and expression of the T cell receptor genes β, α, and γ in unfractionated normal circulating LGL/NK cells, in phenotypically distinct normal LGL/NK cell subsets, and in neoplastic LGL/NK cell proliferations (TγLPD). The normal circulating LGL/NK cells and the phenotypically diverse LGL/NK subsets that we analyzed, including the T cell–like $CD8^{+}$, $CD2^{+}$ subset, displayed the germline configuration and/or lacked expression of the T cell receptor β, α, and γ genes. The lack of T_{β}/T_{α} rearrangement/expression together with the lack of CD3 antigen expression confirms the notion that LGL/NK immune function is clearly distinct from T cell immune function. The lack of T_{γ} gene rearrangement/expression in LGL/NK cells and subsets strongly suggests that LGL/NK cells are ontogenically distinct from T cells because T_{γ} gene rearrangements are believed to represent a very early event during thymic development.[14] Taken together, these data favor the hypothesis that LGL/NK cells represent a cell lineage that is independent and distinct from the T cell lineage. In further support of this conclusion, it has recently been shown that C.B-17 *scid* mice that lack functional T and B cells and whose bone marrow fails to repopulate the thymus have a normal content of NK progenitor cells in the bone marrow.[48]

TγLPD are believed to represent the transformed counterparts of normal LGL/NK cells. Yet, we observed heterogeneity of the TγLPD cases analyzed with respect to their expression of the CD3 antigen and the organization of the T_{β} and T_{γ} loci. The minority of cases (2/17) were $CD3^{-}$ and shared important immunogenotypic, phenotypic, and functional properties with normal circulating LGL/NK cells. They showed germline organization of the T_{β} and T_{γ} genes, an absence of CD3 antigen expression, expression of the Fc_{γ} receptor, and in vitro NK/ADCC activity. Thus, these cases may represent the neoplastic correlate to the major circulating LGL/NK cell population. The remaining 15 cases of TγLPD displayed a combination of the phenotypic, functional, and immunogenotypic properties seen in both T cells and LGL/NK cells but distinct from any single subset of LGL/NK cells that we have analyzed (Tables 1 and 2). Specifically, they all showed T_{β} and T_{γ} gene rearrangements and CD3 antigen expression, typical of mature T cells. They also expressed the Fc_{γ} receptor and exhibited NK and/or ADCC activity, typical of LGL/NK cells.

On the basis of the combined functional, phenotypic, and genotypic analysis of normal and neoplastic T lymphocytes and LGL/NK cells, three distinct populations can be identified: (*a*) major histocompatibility complex (MHC)-restricted T cells and peripheral T cell neoplasms, CD3$^+$, Fc$_\gamma^-$, T$_\beta^+$, T$_\gamma^+$, ADCC$^-$; (*b*) MHC-nonrestricted LGL/NK cells and two of 17 TγLPD, CD3$^-$, Fc$_\gamma^+$, T$_\beta^-$, T$_\gamma^-$, ADCC$^-$; and (*c*) 15 of 17 TγLPD, CD3$^+$, Fc$_\gamma^+$, T$_\beta^+$, T$_\gamma^+$, ADCC$^+$. This raises the question of the relationship of the majority of TγLPD populations, the CD3$^+$ Fc$_\gamma^+$ T$_\gamma$LPD cells, to normal T cells and/or LGL/NK cells. They may represent T cells or LGL/NK cells that have acquired atypical properties during the transformation process or the neoplastic expansion of a separate normal cellular counterpart. Although several authors have reported that Fc$_\gamma$ receptors are not present on the surface of CD3$^+$ T lymphocytes isolated from peripheral blood, concanavalin A–activated cultures, or mixed lymphocyte response cultures,[49-51] the coexistence of Fc$_\gamma$ receptors and CD3 antigen has been reported in selected conditions, eg, the peripheral blood of patients with lymphoproliferative disorders[52,53] or in a variety of in vitro cultured T cell clones (NK-like clones).[54] This functionally unique subset of cytotoxic mononuclear cells, identified by the coexpression of the CD3 antigen and the Fc$_\gamma$ receptor,[55] may be the normal counterpart of the CD3$^+$, Fc$_\gamma^+$ TγLPD. In normal peripheral blood CD3$^+$, Fc$_\gamma^+$ cells represent a minor, usually undetectable ($<1\%$) lymphoid population,[55] which, given its low frequency, was not amenable to analysis by the Southern and Northern blot techniques used in the present study.

The ontogenic relationship between the CD3$^+$, Fc$_\gamma^+$ cell type (TγLPD or NK-like T cells) and T cells or LGL/NK cells bears consideration. Conflicting data have been reported with respect to this issue. Hercend et al reported the isolation of NK-like T cell clones from peripheral T cells,[54] which lent credence to the hypothesis of an ontogenic relationship between T cells and NK-like T cells. However, NK clones bearing rearranged and expressed T cell receptor genes were isolated from the spleens of athymic nude mice by Ikuta et al,[18] which favors the hypothesis of an ontogenic relationship between NK cells and NK-like T cells. In an effort to analyze the relationship between LGL/NK cells and NK-like T cells, in preliminary experiments we have analyzed the in vitro effect of interleukin 2 (IL-2) on purified normal LGL/NK cells. We observed that three to five days after the addition of recombinant IL-2 to the culture the majority of the cells were CD3$^+$, T$_\beta^+$, T$_\alpha^+$, T$_\gamma^+$ and displayed all the functional (NK and ADCC activity) and phenotypic (AB8.28 and HNK-1 antigens) features of LGL/NK cells (unpublished observations). Thus, as suggested by Ikuta et al,[18] CD3$^+$, T$_\beta^+$, Fc$_\gamma^+$ cells may represent a maturative step of LGL/NK cells and may provide a rationale for the ontogenic relationship between the majority of TγLPD and normal LGL/NK cells.

Several recent papers[43-44,56] have described a small population of CD3$^+$, WT31$^-$, CD4$^-$, CD8$^-$ T lymphocytes that have rearranged T$_\gamma$ genes, express T$_\gamma$ protein on the cell surface, and display non–MHC-restricted cytotoxic activity and ADCC. These findings raise the question of the role of the T$_\gamma$ gene product in NK or NK-like cytotoxicity. Our observations that LGLs, which account for virtually all peripheral blood NK activity, maintain the T$_\gamma$ gene in its germline configuration and that CD3$^+$, CD8$^+$, TγLPD with non–MHC-restricted cytotoxicity express T$_\alpha$ and T$_\beta$ mRNAs and display WT31 reactivity suggest that the expression of a T$_\gamma$-containing antigen recognition structure is not an absolute requirement for non–MHC-restricted cytotoxicity.

ACKNOWLEDGMENT

We thank Dr Ellis Reinherz for the T3 MoAb, Dr Abo for the HNK-1 MoAb, Dr G. Trinchieri for the B73.1 MoAb, Dr Malavasi for the AB8.28 MoAb, Dr J. Griffin for the N901 MoAb, Dr W.J.N. Tax for the WT31 MoAb, and Dr Tak Mak for the T$_\beta$ YTJ-2 and T$_\alpha$ PY1.4 clones. We thank Angela Ubriaco and Laurie McFall for excellent technical assistance.

Ultrastructural Analysis of Murine Megakaryocyte Maturation In Vitro: Comparison of Big-Cell and Heterogeneous Megakaryocyte Colonies

By Paula E. Stenberg and Jack Levin

Two morphologically distinct types of murine megakaryocyte (MK) colonies are present after three to seven days in soft agar culture: (*a*) "big-cell" colonies composed of ten to 30 large, mature-appearing megakaryocytes and (*b*) "heterogeneous" colonies consisting of approximately 100 or more cells at various stages of differentiation. Cytochemical and immunocytochemical techniques were used to study MK maturation in colonies as well as normal mouse bone marrow. Acetylcholinesterase (AChE), a specific marker for murine platelets and MK, was found in the perinuclear cisterna, endoplasmic reticulum, and occasionally, Golgi cisternae of MK in three-day big-cell colonies and immature bone marrow MK. MK in seven-day big-cell colonies and mature bone marrow MK showed additional reaction sites in the demarcation membrane system and occasional granules. In seven-day heterogeneous colonies, small cells resembled immature bone marrow MK with respect to AChE localization, whereas large cells corresponded to mature bone marrow MK. With immunogold procedures at the ultrastructural level, polyclonal antibodies against human platelet membrane glycoprotein IIIa and antimouse platelet antiserum labeled bone marrow MK and all MK from colonies grown in soft agar cultures for three to seven days. Granulocytes and macrophages in both bone marrow and soft agar cultures were negative for AChE and these immunocytochemical markers. These data indicate that the pattern of expression of AChE during maturation of MK is similar in vivo and in vitro and demonstrate, when using this marker at the fine-structural level, that a greater range of MK maturational stages is present in heterogeneous colonies than is observed in MK in big-cell colonies. Furthermore, we have confirmed that small cells in heterogeneous colonies are MK and that these colonies are composed solely of MK and their precursors.

© *1987 by Grune & Stratton, Inc.*

TECHNIQUES HAVE EMERGED that permit the identification and study of immature megakaryocytes. One technique is the ability to support proliferation and differentiation of the progeny of megakaryocyte progenitors (megakaryocyte colony–forming cells, Meg-CFC) in vitro, in agar,[1] in methyl cellulose,[2] or in a plasma clot.[3] At least two types of murine megakaryocyte colonies have been recognized in soft agar cultures.[4-8] One type is typically composed of ten to 30 large megakaryocytes that are mature in appearance ("big-cell" type). The other ("heterogeneous" type) is composed of more cells (often >100), some of which are small and immature as evaluated in part by staining for acetylcholinesterase (AChE). In contrast to big-cell colonies, heterogeneous colonies markedly increase in size after their initial appearance.[5,8] Because both types of colonies appear simultaneously in agar cultures, they are probably the progeny of different populations of precursors.[5,8] An important feature of soft agar cultures is that entire, intact megakaryocyte colonies, without contamination by other cell types, may be obtained for the study of megakaryocyte maturation.

The second technique uses markers specific for the megakaryocyte/platelet lineage to identify immature megakaryocytes on a phenotypic basis. AChE staining has proved extremely useful in the identification of cat,[9,10] rat,[9-11] and murine[9,10,12] platelets and megakaryocytes. More recently, antibodies specific for platelet membrane glycoproteins have been used in the identification of human[13-17] and murine[18] megakaryocytes in vivo and in vitro. When immunofluorescence techniques and antibodies directed against platelet glycoproteins were used, both small megakaryocyte precursors and mature megakaryocytes were labeled.[13,15-17,19] At present, however, only limited morphological observations of megakaryocytes in tissue culture systems (particularly those obtained from soft agar culture systems) have been reported.[18,20,21] Specific markers have been used in in vitro systems for studies of the transitional maturational stages between Meg-CFC and megakaryocytes. For example, it has been demonstrated in the mouse that the small AChE-positive cell represents an intermediate stage between Meg-CFC and mature megakaryocytes,[12,22,23] and small cells expressing platelet glycoproteins or cytoplasmic factors have been described in humans both in vitro (in plasma clot cultures) and in vivo.[13,15-17,24] More recently, an immunofluorescence study by Levene et al[25] has suggested expression of platelet glycoprotein IIb/IIIa at the level of the committed megakaryocyte progenitor because an antibody directed against the platelet glycoprotein IIb/IIIa complex inhibited the growth of human megakaryocyte colonies. Another study by Fraser et al[26] has presented evidence that the human pluripotential hematopoietic stem cell expresses platelet lineage–specific markers.

In our previous paper[18] using specific markers at the light microscope level, we observed immunoperoxidase label in most immature cells of megakaryocyte colonies on 2-μm-thick plastic sections. In this investigation, we used specific markers at the fine-structural level to more fully characterize megakaryocytes grown in soft agar cultures because this allows the examination of patterns of protein expression

in megakaryocytes at early time points in culture (and hence presumably at various stages of differentiation) and, particularly, the study of small, immature cells that partially constitute the heterogeneous megakaryocyte colonies. In contrast to bone marrow cell suspensions, these megakaryocyte colonies permit the study of purified populations of cells of the megakaryocytic lineage at different stages of maturation, without the requirement for initial physical separation from other cell lineages. We specifically compared at the ultrastructural level the pattern of expression of AChE and the distribution of plasma membrane glycoproteins in heterogeneous megakaryocyte colonies and big-cell megakaryocyte colonies to determine whether this system might be useful to study megakaryocyte differentiation.

MATERIALS AND METHODS

Mice

C57BL/6J mice, obtained from Simonsen Laboratories, Inc (Gilroy, CA), were used for these experiments. These mice were bred under specific pathogen-free conditions and then maintained under conventional conditions.

Preparation of Murine Bone Marrow Samples

Mouse femoral marrow samples were obtained from animals killed by cervical dislocation. A 25-gauge needle was inserted into the proximal end of the femur, and fixative was gently pushed through the length of the bone to remove the marrow core. The marrow cells were dispersed into a single-cell suspension by gentle pipetting. The cells were fixed in either 1.44% glutaraldehyde in 0.1 mol/L cacodylate buffer, pH 6.8, for 1.5 hours at ambient temperature for AChE staining or in 2% paraformaldehyde with 0.05% glutaraldehyde in 0.1 mol/L phosphate buffer, pH 7.4, for two hours at ambient temperature for immunocytochemical staining.

Preparation of Murine Megakaryocyte Colonies

Spleen cells were obtained as previously described,[27] and these were used rather than bone marrow because spleen cells produce a greater proportion of megakaryocyte colonies. Cultures of spleen cells were maintained in 0.3% agar in Dulbecco's modified Eagle's medium as described previously.[27] The final concentration of horse serum was 20%. One milliliter of a splenic cell suspension in agar medium was cultured with 0.1 mL of pokeweed mitogen stimulated, spleen cell–conditioned medium and incubated for three to seven days in a humidified atmosphere of 10% CO_2 in air. In this culture system, megakaryocyte colonies achieve their maximum frequency and ploidy (DNA) levels after seven days.[5,27] At various times, colonies were removed from culture dishes with a finely drawn Pasteur pipette and placed either in a vial containing fixative or a small drop of fixative. In the latter case, an equal volume of warm 3% agar was layered onto the colony-fixative drop, allowed to harden, and removed as a disc into a Petri dish of fixative. Fixatives were as described earlier. Granulocyte and macrophage colonies, which also were present in this culture system, were similarly obtained and studied. After fixation, the samples were rinsed in the appropriate wash buffer.

Cytochemical Procedures for Detection of AChE

AChE cytochemistry was performed on suspensions of bone marrow cells or colonies obtained from soft agar cultures by using the technique of Tranum-Jensen and Behnke[22] as modified by Paulus et al.[28] Control preparations included the omission of substrate or the substitution of butyrylthiocholine iodide for acetylthiocholine iodide (Sigma Chemical Co, St Louis). Other samples were preincubated and stained in the presence of 10^{-5} mol/L eserine (Sigma), an inhibitor of both AChE and nonspecific cholinesterase. The samples were then processed for electron microscopy.

Immunocytochemical Procedures

Immunocytochemical procedures on suspensions of bone marrow cells or colonies obtained from soft agar culture were performed as follows. After fixation, the cells were rinsed several times in 0.1 mol/L phosphate buffer, pH 7.4, with 50 mmol/L NH_4Cl and 2% sucrose. They then were incubated with rabbit antihuman glycoprotein IIIa serum (a gift of Dr Rodger P. McEver, San Antonio, TX) or rabbit antimouse platelet antiserum (PAS)[18] (both of which were diluted 1:500 in phosphate-buffered saline) overnight at 4°C. We have previously demonstrated that antisera directed against human platelet antigens identify murine megakaryocytes.[18] Rabbit antimouse PAS was prepared and carefully absorbed with both RBC and WBC as described previously,[27] and an immunoblot assay with solubilized platelet proteins as the target antigens demonstrated that this PAS was active against multiple murine platelet proteins ranging from less than 45 kilodaltons (kD) to more than 300 kD, the resolving limits of the gel system.[29] The most intense labeling occurred against the region of the gel that contained the platelet glycoprotein IIb/IIIa complex. Microscopy with immunoperoxidase–labeled reagents demonstrated no reactivity of the PAS against nonmegakaryocytic bone marrow cells or granulocyte or macrophage colonies,[18] whereas megakaryocytes of all maturational stages were labeled by this polyclonal PAS.[18]

Subsequently, bone marrow cells or colonies were rinsed in phosphate-buffered saline several times and then incubated with protein A–gold probes (5-, 10-, or 15-nm-sized particles) (Janssen Pharmaceuticals, Beerse, Belgium) diluted 1:20 in 20 mmol/L Tris buffer, pH 8.2, with 0.9% NaCl and 0.1% bovine serum albumin. The samples were rinsed four times with the same Tris buffer and then fixed in 1.5% glutaraldehyde in 0.1 mol/L cacodylate buffer, pH 7.4, with 1% sucrose for 45 minutes. They were left overnight at 4°C in 0.1 mol/L cacodylate buffer, pH 7.4, with 1% sucrose and then processed for electron microscopy as will be described. Control procedures included the substitution of irrelevant antibodies, buffer, or preimmune serum for the primary antibodies.

Preparation of Bone Marrow and Colony Samples for Transmission Electron Microscopy

Fixed, stained samples were osmicated (2% OsO_4 in veronal-acetate buffer) and then dehydrated in a graded series of ethanol, infiltrated with propylene oxide, and embedded in Epon. Thin sections (100 nm) were cut, stained with either uranyl acetate and lead citrate or lead citrate alone, and examined with a Philips EM-201 transmission electron microscope.

RESULTS

Classification of the maturational stages of megakaryocytes is complex because cytoplasmic and nuclear development are not synchronous events. The present study is primarily based on the system proposed by Paulus[30] in his ultrastructural studies of guinea pig megakaryocytes and used by Bentfeld-Barker and Bainton in their ultrastructural studies of rat and human megakaryocytes.[31,32] In brief, immature megakaryocytes are small cells measuring 6 to 24 µm in the long axis,[33] containing a large, round, indented, or lobed nucleus[23] with prominent nucleoli, and having a high nuclear:cytoplasmic ratio. These cells contain few cytoplasmic organelles other than polyribosomes and mitochondria.

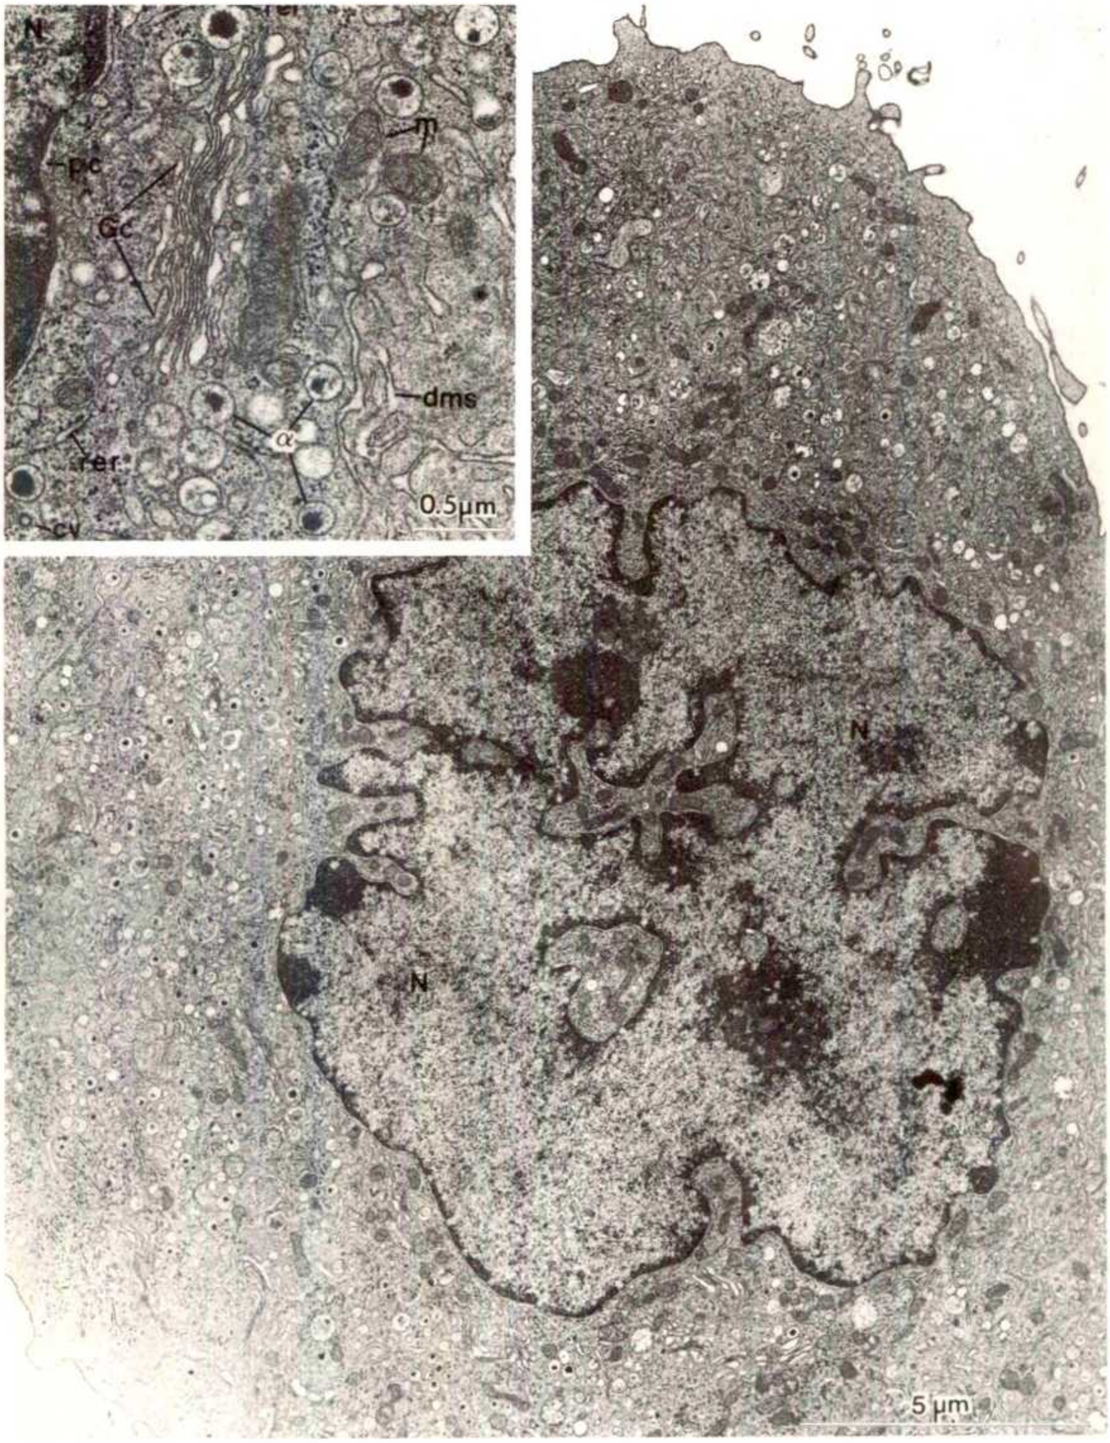

Fig 1. A mature mouse megakaryocyte obtained from a seven-day big-cell megakaryocyte colony. The abundant cytoplasm contains numerous profiles of rough endoplasmic reticulum, demarcation membranes, mitochondria, and α granules, which resembles that of a mature mouse bone marrow megakaryocyte. At higher magnification of the Golgi region of this cell (insert), several cisternae of the Golgi complex (Gc) are evident. Many α granules (α) can be identified in this field. N, nucleus; rer, rough endoplasmic reticulum; dms, demarcation membrane system; cv, coated vesicle; m, mitochondria; pc, perinuclear cisterna (original magnification ×8,000; inset, ×25,000; current magnification ×7,440; inset ×23,250).

Maturing megakaryocytes are heterogeneous in size (14 to 30 μm)[33] and in the level of polyploidy (8 to 32N). They contain a large protein synthetic apparatus and variable numbers of demarcation membranes and α granules. Mature megakaryocytes are approximately 20 to 50 μm in diameter[33] with a low nuclear:cytoplasmic ratio and contain an extensive demarcation membrane system and a reduced protein synthetic apparatus. In contrast to murine bone marrow in which immature megakaryocytes constitute only a small proportion of the cells and are difficult to identify without the use of specific markers, megakaryocyte colonies from soft agar cultures allow the study of sufficient populations of cells of the megakaryocyte lineage that may be more precisely evaluated (ie, in regard to age) than in the bone marrow.

Megakaryocyte colonies present after seven days in soft agar culture (at which time the maximum number of megakaryocyte colonies has been reached) were composed of megakaryocytes at various stages of maturation, from immature to mature cells. Morphologically, mature cells in big-cell and heterogeneous colonies (Fig 1) resembled bone marrow megakaryocytes with the following exceptions. These cells had greater numbers of multivesicular bodies, which presumably contain agar ingested from the surrounding culture medium, than bone marrow megakaryocytes. Additionally, the number of α granules that were uncondensed was greater in megakaryocytes in colonies than in bone marrow megakaryocytes. The size of mature megakaryocytes in seven-day colonies approximated the size of mature bone marrow megakaryocytes, although no evidence of platelet production was observed. At least two thirds of maturing (Fig 2) and mature megakaryocytes examined from both big-cell and heterogeneous colonies contained demarcation membranes only in one area of the cell cytoplasm. These membranes had fewer connections to the megakaryocyte plasma membrane and compartmentalized less cytoplasm than did membranes in bone marrow megakaryocytes. Areas of these demarcation membranes in cells from colonies did not contain many other organelles such as mitochondria and α granules in contrast to bone marrow megakaryocytes, which exhibited a more uniform distribution of organelles. The appearance of these cells partially resembled that of megakaryocytes described previously by Zucker-Franklin and Petursson.[34]

Distribution of AChE in Murine Bone Marrow Megakaryocytes and Megakaryocytes in Soft Agar Culture

Bone marrow megakaryocytes. In immature mouse bone marrow megakaryocytes, reaction product for AChE was confined to the perinuclear cisterna and endoplasmic reticulum (Fig 3A). Few granules and demarcation membrane system profiles were observed in these cells and, if present, were generally unreactive. Occasionally, mouse erythroblasts also demonstrated AChE reaction product in the perinuclear cisterna and endoplasmic reticulum, as reported previously by Paulus et al.[28] In mature mouse bone marrow megakaryocytes, reaction product for AChE was observed in the perinuclear cisterna, endoplasmic reticulum, some cisternae of the Golgi complex, some profiles of the demarcation membrane system, and occasional granules (Fig 3B). All other bone marrow cells including eosinophils were completely unreactive for AChE. Control samples in which specific substrate was either omitted or substituted with butyrylthiocholine or in which preincubation and incubation with eserine was performed resulted in megakaryocytes that were negative for AChE (not shown).

Megakaryocytes in colonies in soft agar culture. Most megakaryocytes in colonies, after three days of soft agar culture, were immature in appearance with a high nuclear:cytoplasmic ratio and few cytoplasmic organelles.

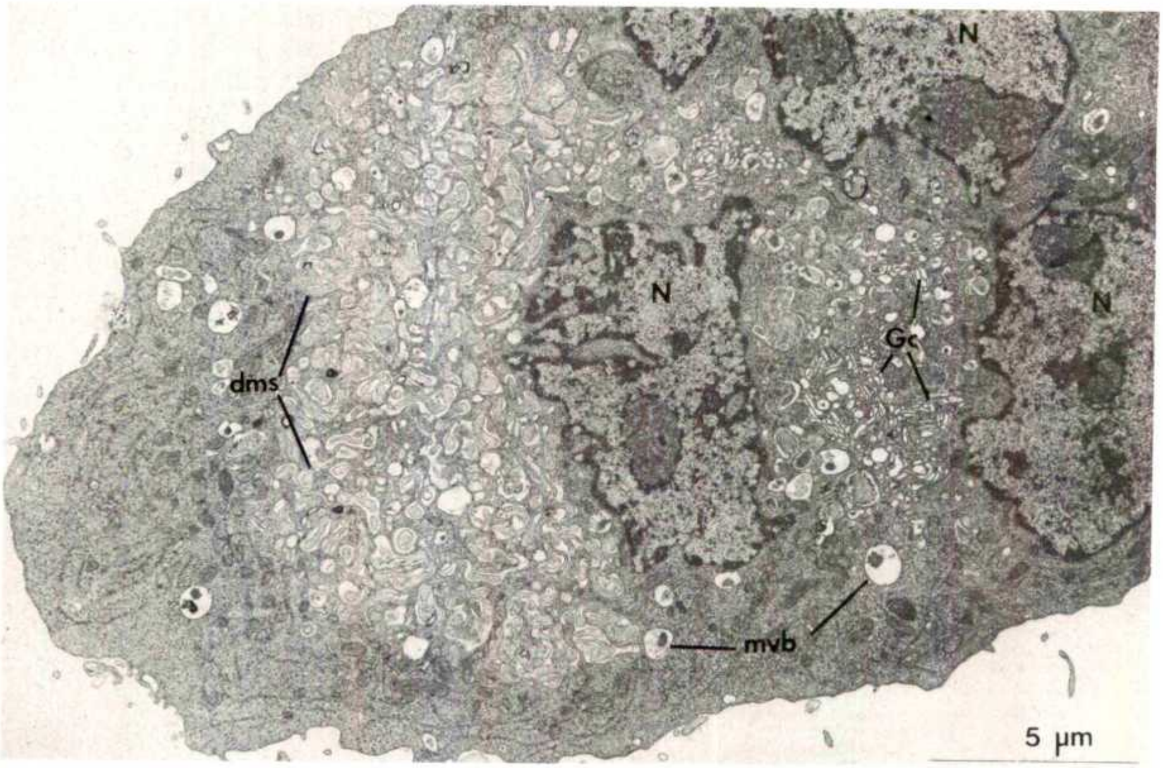

Fig 2. A maturing mouse megakaryocyte obtained from a four-day big-cell megakaryocyte colony. The demarcation membrane system (dms) is concentrated in one area of the cell cytoplasm and contains few other organelles. N, nucleus; Gc, Golgi complex; mvb, multivesicular body (original magnification ×6,000).

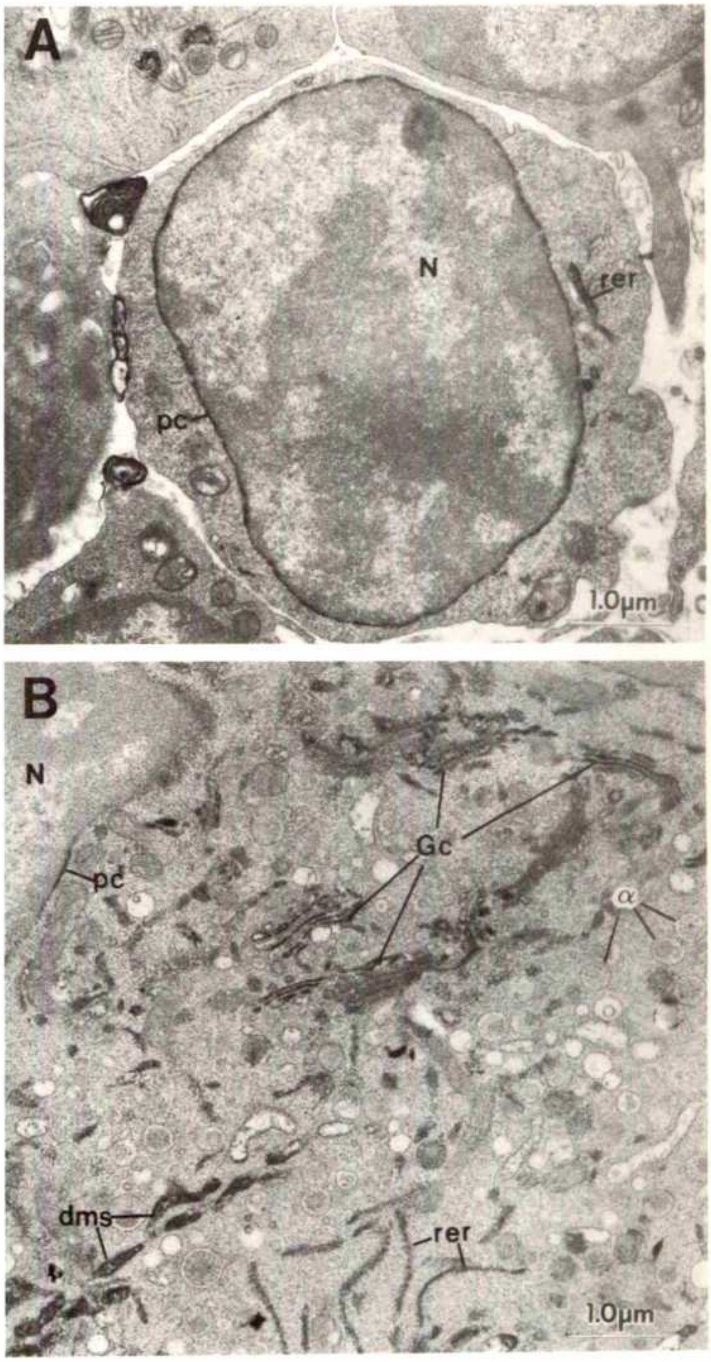

Fig 3. (A) An immature mouse bone marrow megakaryocyte reacted for AChE. Reaction product is confined to the perinuclear cisterna (pc) and rough endoplasmic reticulum (rer). No granules or demarcation membranes are observed (original magnification ×13,500; current magnification ×12,555). (B) A mature mouse bone marrow megakaryocyte reacted for AChE. Reaction product is present in the perinuclear cisterna (pc), rough endoplasmic reticulum (rer), some cisternae of the Golgi complex (Gc), and some profiles of the demarcation membrane system (dms). α Granules (α) are unreactive. N, nucleus (original magnification ×13,500; current magnification ×12,555).

These cells contained reaction product for AChE within the perinuclear cisterna and endoplasmic reticulum (Fig 4A). Occasional megakaryocytes were observed in three-day big-cell colonies, which were considerably more mature and larger in size and contained reaction product in the perinuclear cisterna, many profiles of endoplasmic reticulum, and some cisternae of the Golgi complex (not shown). Megakaryocytes in seven-day big cell colonies resembled mature megakaryocytes in bone marrow with respect to the distribution of AChE. Megakaryocytes in seven-day heterogeneous colonies varied considerably in size and stage of maturation. Small megakaryocytes from these colonies resembled immature megakaryocytes from three day big-cell colonies. All small megakaryocytes examined contained AChE reaction product in the perinuclear cisterna, endoplasmic reticulum (Fig 4B), and some cisternae of the Golgi complex, if this organelle was present. In contrast to data obtained earlier[5] that showed these small cells to be 2N or 4N in ploidy and AChE-negative, we observed positive label in every cell examined at the ultrastructural level. This may be explained by the greater sensitivity of the ultrastructural cytochemical technique as compared with the light microscope level technique. Furthermore, increasing the time of incubation with substrate to 6 hours has demonstrated that all cells in

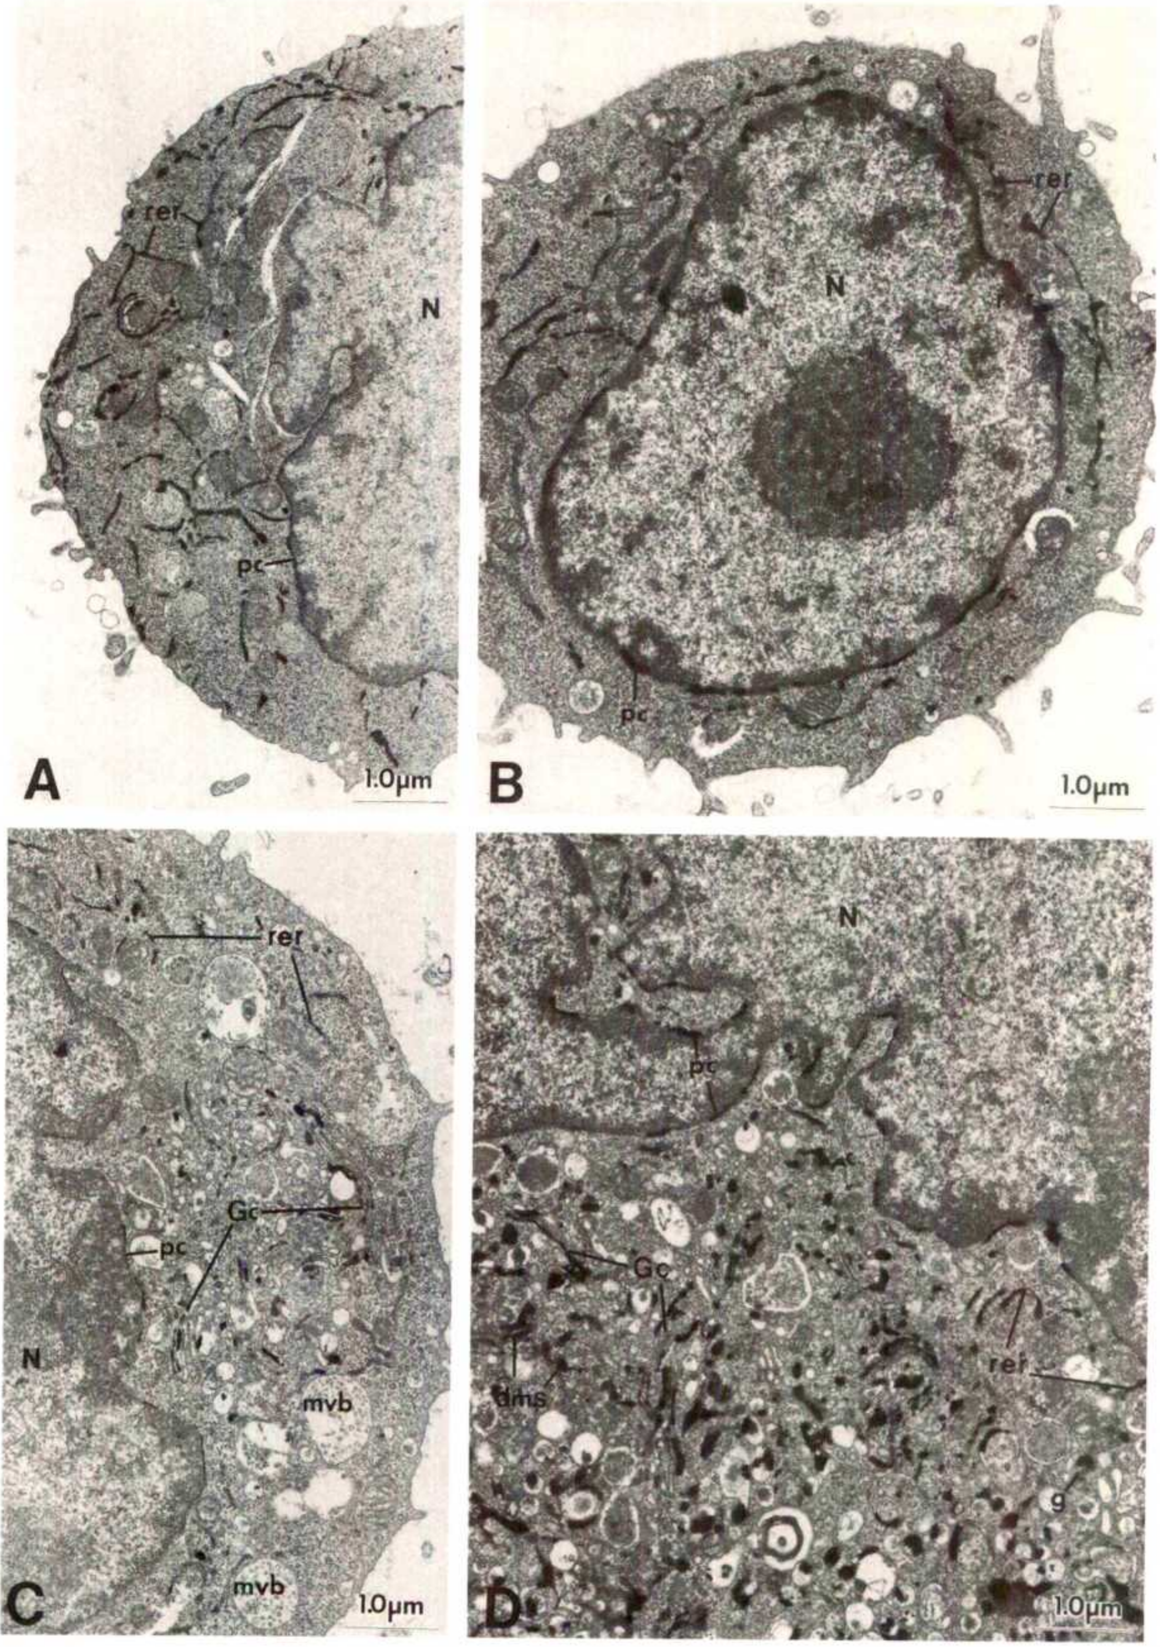

Fig 4. (A) An immature mouse megakaryocyte from a three-day big-cell megakaryocyte colony reacted for AChE. As in Fig 2A, reaction product is confined to the perinuclear cisterna (pc) and rough endoplasmic reticulum (rer) (original magnification ×13,000; current magnification ×12,090). (B) An immature mouse megakaryocyte from a seven-day heterogeneous colony reacted for AChE. As in Figs 2A and 3A, reaction product is found in the perinuclear cisterna (pc) and rough endoplasmic reticulum (rer) (original magnification ×13,000; current magnification ×12,090). (C) A maturing megakaryocyte from a seven-day heterogeneous colony reacted for AChE. Reaction product is present in the perinuclear cisterna (pc), some cisternae of the Golgi complex (Gc), and some profiles of the rough endoplasmic reticulum (rer). Very few demarcation membranes or granules are present in this cell (original magnification ×13,000; current magnification ×12,090); mvb, multivesicular body. (D) A mature megakaryocyte from a seven-day heterogeneous colony reacted for AChE. Reaction product is distributed similarly to mature bone marrow megakaryocytes: perinuclear cisterna (pc), rough endoplasmic reticulum (rer), Golgi complex (Gc), demarcation membrane system (dms), and some granules (g) are labeled. The dms is thicker than the rer. The marked increase in the size of megakaryocytes as they mature in culture is clearly shown by the increased area occupied by the cells in this figure, each of which is shown at the same magnification (original magnification ×13,000; current magnification ×12,090). N, nucleus.

heterogeneous colonies are AChE-positive at the light microscopic level (J. Levin and F. Levin, unpublished observations). Maturing and mature megakaryocytes from seven-day heterogeneous colonies resembled maturing and mature bone marrow megakaryocytes with respect to the distribution of AChE (Figs 4C and 4D). Cells from granulocyte or macrophage colonies grown for three to seven days in soft agar culture were negative for AChE (not shown).

Distribution of Plasma Membrane Glycoproteins in Murine Bone Marrow Megakaryocytes and Megakaryocytes in Soft Agar Culture

Bone marrow megakaryocytes. Mature, recognizable bone marrow megakaryocytes exhibited extensive immunogold label along their plasma membranes when cell suspensions were incubated with either PAS or antiglycoprotein IIIa antibodies and any of the three sizes of protein A–gold probe used, although the greatest amount of label was obtained with PAS followed by protein A–gold (particle size, 5 nm; not shown). All other bone marrow cells were completely negative. Control samples of all bone marrow cells including megakaryocytes in which normal rabbit serum or buffer was substituted for specific primary antibodies also were negative (not shown).

Megakaryocytes in colonies in soft agar culture. All megakaryocytes in either big-cell or heterogeneous colonies after three to seven days in soft agar culture showed immunogold label for PAS or glycoprotein IIIa along the extent of the plasma membrane, regardless of their stage of maturation (Fig 5 and Figs 6A and B). Megakaryocytes in colonies demonstrated a lower concentration of gold particles along plasma membranes than mature bone marrow cells. Although these experiments were technically difficult to perform, all of the immunoreagents passed through the thin agar shell surrounding the colonies.

DISCUSSION

We have investigated the maturation of murine megakaryocytes in soft agar cultures at the ultrastructural level with respect to their morphological appearance and the distribution of AChE and plasma membrane glycoproteins and determined that both big-cell and heterogeneous colonies contain only megakaryocytes. Immature cells in three-day big-cell colonies, seven-day heterogeneous colonies, and bone marrow demonstrated reaction product for AChE predominantly in the perinuclear cisterna and endoplasmic reticulum and also in Golgi cisternae, if present. In contrast, large megakaryocytes from seven-day big-cell and heterogeneous megakaryocyte colonies and mature bone marrow cells were much more reactive than immature cells, with reaction product present in the perinuclear cisterna, endoplasmic reticulum, Golgi complex, demarcation membrane system, and some granules. All cells in megakaryocyte colonies, regardless of the time in culture or extent of morphological maturity, exhibited immunogold label along the plasma membrane with PAS or anti–GP IIIa serum. Importantly, cells in big-cell colonies achieve their ultimate mean ploidy distribution four days after the initiation of cultures, whereas

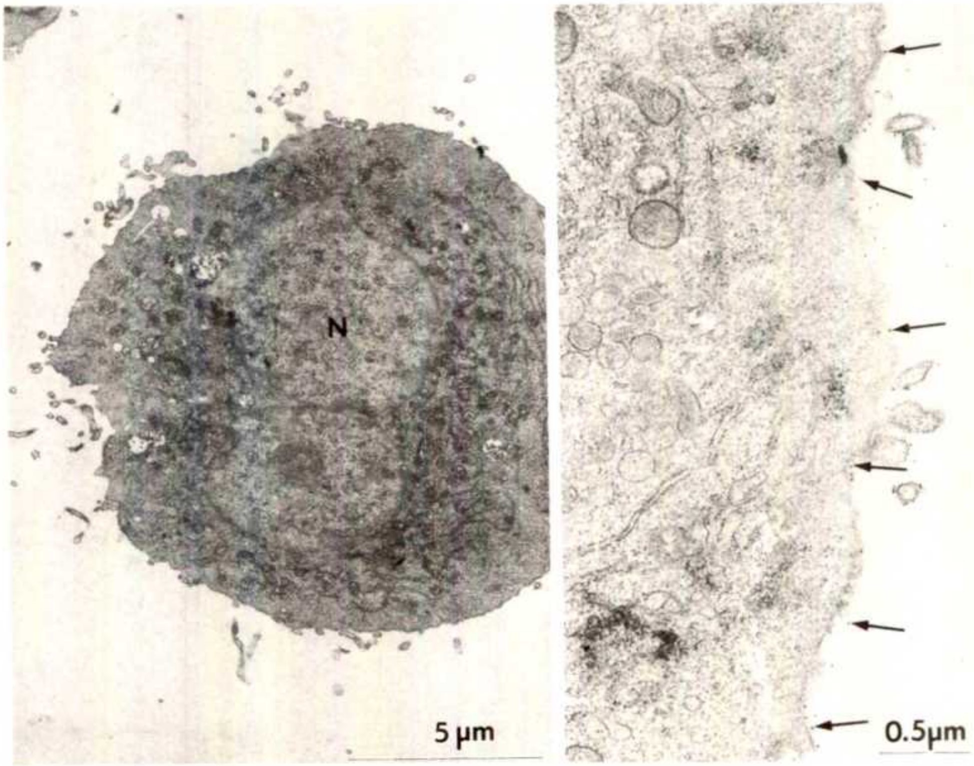

Fig 5. An immature megakaryocyte from a three-day big-cell colony reacted with PAS followed by protein A–gold (size, 10 nm) probe. At higher magnification (inset) the immunogold label is clearly evident along the plasma membrane (arrows). This cell has a high nuclear:cytoplasmic ratio and no dms profiles (original magnification ×5,000; inset ×21,000).

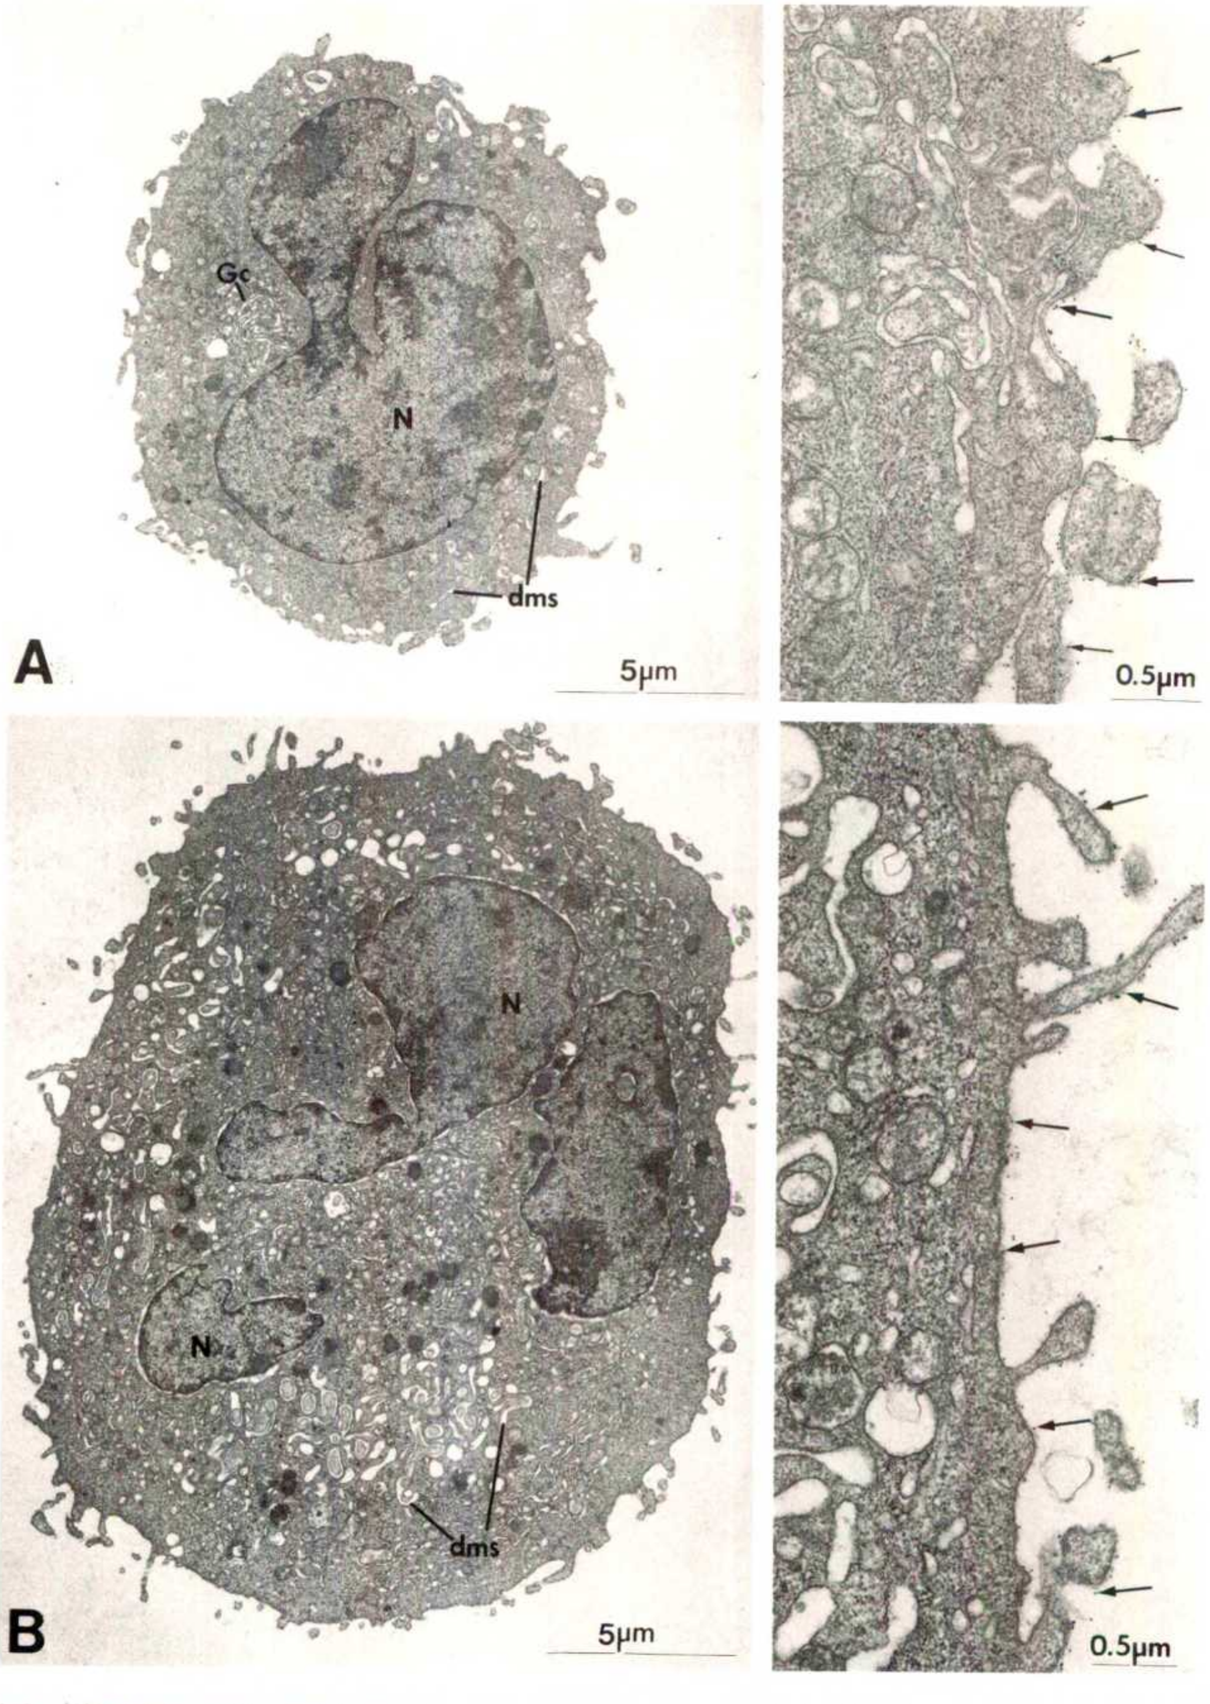

Fig 6. (A) Immature megakaryocyte from a seven-day heterogeneous colony reacted with PAS followed by a protein A–gold (size, 10 nm) probe. At higher magnification (inset) the immunogold label is clearly evident along the plasma membrane (arrows). This cell has a high nuclear:cytoplasmic ratio and only a few dms profiles (original magnification ×5,000; inset ×21,000). (B) Maturing megakaryocyte from a seven-day heterogeneous colony reacted with PAS followed by a protein A–gold (size, 10 nm) probe. Note that this cell is larger, with a lower nuclear:cytoplasmic ratio, and contains more demarcation membranes than the cell in (A). The large, dense granules are multivesicular bodies. At higher magnification (inset) the immunogold label is seen along the plasma membrane at a concentration comparable to that seen in (A) (original magnification ×5,000; inset ×21,000). N, nucleus; dms, demarcation membrane system; Gc, Golgi complex.

the mean ploidy level of heterogeneous colonies continues to increase after four days of culture.[5] Therefore, megakaryocytes express lineage-specific glycoproteins before they attain their final polyploid stage. Pertinently, although heterogeneous colonies are derived from a single precursor cell, they are comprised of megakaryocytes at different stages of maturation (as determined by morphological appearance, size, and AChE localization) in contrast to megakaryocytes in big-cell colonies, which are more uniformly mature in appearance. Because approximately half of the cells in heterogeneous colonies contain 2N or 4N levels of DNA,[5,6] our current fine-structural studies further indicate that cells at low ploidy levels express AChE[35] and lineage-specific membrane glycoproteins.

Previously, staining for AChE has been used to identify immature mouse megakaryocytes.[11,12,23,36] Ultrastructural studies have localized AChE to the protein synthetic apparatus and in a population of granules distinct from α granules in rodent bone marrow megakaryoblasts and megakaryocytes.[10,28] Similarly, we have localized AChE in the endoplasmic reticulum, nuclear envelope, and Golgi complex of immature mouse marrow megakaryocytes and immature megakaryocytes from colonies in soft agar culture. Tranum-Jensen and Behnke also localized AChE to the Golgi complex and profiles of endoplasmic reticulum in small, immature bone marrow cells (6 to 8 μm in diameter), which they considered to be megakaryocyte precursor cells.[22] As previously reported for bone marrow cells,[10,28] the Golgi complex, endoplasmic reticulum, and nuclear envelope as well as demarcation membranes and some granules were labeled in more mature megakaryocytes in soft agar culture. Reaction product in the Golgi complex of cells examined in our study was sometimes confined to only one face of the Golgi complex or was present throughout the Golgi complex, as Tranum-Jensen and Behnke also have previously reported.[10] Therefore, AChE is synthesized and packaged into granules in megakaryocytes maturing in soft agar culture, similarly to megakaryocytes in vivo. This perhaps supports the suggestion of Paulus et al[28] that cholinergic regulation may be involved in the control of megakaryocyte growth and therefore operative both in vivo and in vitro. Additional support for this hypothesis is obtained from the report of Burstein et al[37] that cholinergic agonists increase the frequency of megakaryocyte colonies in vitro.

Platelet peroxidase is currently the earliest recognized marker of human megakaryocytes in vivo and in vitro.[3,15] Vainchenker et al[15] and Vinci et al[14] have determined that the glycoprotein IIb/IIIa complex is also an early antigenic marker of human megakaryocyte maturation because it is present in cells five to six days after the initiation of plasma clot cultures. More recently, Jenkins et al[38] have reported that megakaryocytes derived from human committed megakaryocyte progenitor cells in vitro synthesize glycoproteins IIb and IIIa. Jackson has demonstrated that small rat marrow cells expressing AChE activity also were labeled by fluorescent anti-PAS.[39] We have determined that both AChE and lineage-specific membrane glycoproteins are detectable in immature murine megakaryocytes three days after the culture of Meg-CFC in soft agar, the first day of culture in which murine megakaryocyte colonies can be confidently visually identified under the light microscope. Because it is difficult to reliably retrieve megakaryocyte colonies from soft agar cultures before this time, we were unable to determine which of these markers appears first in our culture system.

It is of interest that during neutrophil differentiation some antigens are lost (as identified by monoclonal antibody MY-10 or those to Ia antigen) or acquired (as identified by monoclonal antibodies Mo1, MY8, 8OH.3, or B34.3) as these cells mature from myeloblasts to polymorphonuclear leukocytes, whereas expression of other antigens (as identified by monoclonal antibodies 82H5, R1B19, and S4-7) occurs throughout the neutrophil maturation sequence.[40] Recently, using monoclonal antibodies with light microscopy, Levene et al[25] have identified three maturational levels in the human megakaryocyte lineage with distinct immunologic phenotypes; some monoclonal antibodies recognize epitopes expressed only at certain stages of maturation (eg, on immature megakaryocytes or on both immature and mature megakaryocytes) or that, in contrast, are present throughout the entire megakaryocyte/platelet lineage. Utilization of the soft agar culture system in conjunction with similar probes to examine murine or human megakaryocyte maturation at the ultrastructural level will yield important information concerning the time of expression and localization of specific proteins during the developmental sequence of this cell. Future studies will examine the effects of administration to mice of PAS[5] or 5-fluorouracil,[41] agents known to perturb thrombopoiesis, to obtain additional information about megakaryocyte differentiation.

ACKNOWLEDGMENT

The authors wish to thank Dr Mary Bentfeld-Barker and Dr Dorothy Bainton for helpful discussions and suggestions regarding this work.

Immunoglobulin and T Cell Receptor β Chain Gene Rearrangement Analysis of Ocular Adnexal Lymphoid Neoplasms: Clinical and Biologic Implications

By Antonino Neri, Frederick A. Jakobiec, Pier-Giuseppe Pelicci, Riccardo Dalla-Favera, and Daniel M. Knowles, II

We investigated the organization of the immunoglobulin heavy chain (IgH) and the T cell receptor beta chain (Tβ) gene loci in 20 ocular adnexal and four extraocular lymphoid neoplasms obtained from 18 patients presenting with an ocular adnexal lymphoid neoplasm. Fifteen ocular adnexal and four extraocular lymphoid neoplasms occurring in 13 patients were classified by morphological examination and immunophenotypic analysis as monoclonal B cell lymphomas. Each one of these 19 lymphoid neoplasms exhibited clonal IgH gene rearrangements upon hybridization of *Eco*RI- or *Hind*III-digested DNA to a heavy-chain joining region (J_H)-specific DNA probe. The bilateral ocular adnexal monoclonal B cell neoplasms occurring simultaneously in two individuals exhibited identical clonal IgH gene rearrangements, which indicated their derivation from an identical B cell clone. The ocular adnexal and the extraocular monoclonal B cell neoplasms occurring in two of three patients also exhibited identical clonal IgH gene rearrangements, which suggested that they too were derived from an identical B cell clone. Five ocular adnexal lymphoid neoplasms were classified by morphological examination and immunophenotypic analysis as benign, polyclonal pseudolymphomas. Three of these five ocular adnexal lymphoid neoplasms exhibited clonal IgH gene rearrangements, which suggested the presence of monoclonal B cell populations that escaped detection by morphological and immunophenotypic examination. None of the 24 pathological samples exhibited clonal Tβ gene rearrangements upon hybridization of *Eco*RI- or *Bam*HI-digested DNA to a Tβ gene DNA probe. The results of these studies demonstrate the value of Southern blot hybridization analysis for clonal IgH and Tβ gene rearrangements in the diagnosis, classification, and investigation of extranodal lymphoid neoplasms originating and/or presenting in the ocular adnexa.

EXTRANODAL LYMPHOID INFILTRATES, ie, those that originate and/or present outside of the major lymphoid tissue–bearing sites, often represent a difficult clinical and pathological diagnostic dilemma.[1] This is particularly true for small lymphocytic infiltrates, which constitute the majority of the ocular adnexal and pulmonary lymphoid neoplasms and which also occur in the gastrointestinal tract, skin, salivary glands, and other sites.[1,2] The histopathologic criteria commonly used to distinguish benign and malignant extranodal small lymphocytic infiltrates are often incapable of reliably making this distinction,[3] sometimes resulting in inaccurate patient prognostication. Cell marker analyses have shown that extranodal small lymphocytic infiltrates are largely divisable into monoclonal B cell, presumably malignant, small (well-differentiated) lymphocytic lymphomas and polyclonal, presumably benign, pseudolymphomas.[4,5] However, a recent prospective study suggested that disseminated malignant lymphoma occurs with equal frequency in patients with ocular adnexal lymphoid neoplasms belonging to each category.[2] This finding suggests that immunophenotypic analysis also may be incapable of reliably prognosticating patients with extranodal small lymphocytic infiltrates. Moreover, clinical, morphological, and immunophenotypic approaches have not provided significant insight into the pathogenetic relationship between extranodal pseudolymphoma and malignant lymphoma, between extranodal and nodal lymphoid neoplasms, and among multiple extranodal lymphoid infiltrates occurring in the same individual.

The antigen recognition molecules of B and T cells, immunoglobulin (Ig) and T cell receptor(s), respectively, are encoded by genetic loci that undergo somatic recombinations (rearrangements) to become functionally active in mature lymphocytes.[6-8] We and other investigators have demonstrated that clonal rearrangements of the Ig and the T cell receptor β chain (Tβ) gene loci are accurate and objective molecular genetic markers of the lineage and clonality of B and T cells, respectively.[9-13] The demonstration of clonal Ig and Tβ gene rearrangements by Southern blot hybridization analysis has determined the lineage and the clonality of a variety of lymphoproliferative disorders and has become an important adjunct in the diagnosis, classification, and investigation of lymphoid neoplasias.[14-17] However, immunogenotypic analysis has not been systematically applied to an examination of extranodal small lymphocytic infiltrates.

We investigated the organization of the Ig and the Tβ gene loci in 24 morphologically and immunophenotypically well characterized samples of ocular adnexal, eg, conjunctival, lid, orbital, and extraocular lymphoid neoplasms obtained from 18 patients presenting with an ocular adnexal lymphoid neoplasm. This survey included patients with a solitary, unilateral ocular adnexal lymphoid neoplasm without sys-

Table 1. Clinical Findings in 18 Patients Presenting With Ocular Adnexal Lymphoid Neoplasms

Patient	Age	Sex	Pertinent Prior History	Presentation and Findings	Histopathology	Clonality	Treatment	Clinical Course	Eventual Outcome
1	62	M	36 mo earlier RUL pseudolymphoma; systemic evaluation negative; no therapy	Proptosis, firm nodular RUL mass; systemic evaluation negative	RLH	Polyclonal	Incisional Bx; local irradiation	Asymptomatic	NED: 29 mo
2	55	F	None	7-mo Hx of painless, enlarging LUL; ptosis on LUL, firm mass adherent to orbit; systemic evaluation negative	RLH	Polyclonal	Excisional Bx only	Asymptomatic	43 mo: RUL lymphoid tumor; Bx: DPDL, monoclonal B; local irradiation
3	64	F	None	6-mo Hx of LLL swelling with protrusion of left eye; palpable mass on lower orbital rim with slight proptosis and upward displacement of globe; systemic evaluation negative	RLH	Polyclonal	Subtotal excision only	Asymptomatic	NED: 56 mo
4	51	F	Undocumented Hx of "benign lymphoma" of lung treated by irradiation	36-mo Hx of LLL fullness and 6-mo Hx of LLL swelling; palpable firm LUL fullness; systemic evaluation negative	RLH	Polyclonal	Excisional Bx only	Asymptomatic	NED: 43 mo
5	59	F	None	30-mo Hx of LUL swelling, recent ptosis; CAT scan: left orbital mass; systemic evaluation negative	RLH	Polyclonal	Excisional Bx; local irradiation	Asymptomatic	NED: 44 mo
6	54	M	None	72-mo Hx of right eye prominence; proptosis; systemic evaluation negative	SL	Monoclonal B	Excisional Bx; local irradiation	Asymptomatic	NED: 12 mo
7	64	F	None	4-mo Hx of left ocular proptosis; Firm, rubbery mass on LLL; systemic evaluation negative	IL	Monoclonal B	Excisional Bx; local irradiation	Asymptomatic	NED: 39 mo
8	63	F	Kaposi's sarcoma of lower extremities	2-mo Hx of LUL swelling; firm, nontender, mobile LUL mass; systemic evaluation negative	SL	Monoclonal B	Excisional Bx; local irradiation	Kaposi's sarcoma lesions increase in number	Dead: 46 mo, metastatic lung carcinoma
9	43	M	None	1-mo Hx of RUL ptosis; palpable mass on RUL, RUL ptosis; systemic evaluation negative	DLNC	Monoclonal B	Excisional Bx; systemic chemotherapy for 6 mo	Asymptomatic	NED: 28 mo
10	81	M	None	12-mo Hx of right superior conjunctival mass with occasional blurred vision; firm, salmon-colored lesion on right epibulbar surface extending into superolateral fornix; systemic evaluation negative	SL	Monoclonal B	Excisional Bx; local irradiation	Asymptomatic	NED: 36 mo

11	81	M	2-yr Hx of generalized lymphadenopathy; Bx diagnosis: DPDL	2-mo Hx of painless RUL swelling; firm, salmon-colored mass of superotemporal quadrant; CAT scan: extensive abdominal lymphadenopathy	DLNC	Monoclonal B	Incisional Bx; local irradiation; systemic chemotherapy	Systemic dissemination	Dead: 16 mo, disseminated lymphoma
12	56	F	None	4-mo Hx of RUL mass; firm, rubbery, mobile RUL mass; refused systemic evaluation	SL	Monoclonal B	Excisional Bx; refused further therapy	12 mo: asymptomatic LUL mass; Bx: lymphoma; serum IgMκ spike, refused therapy; 18-mo CAT scan: gastric mass; Bx: lymphoma; systemic chemotherapy	Alive with systemic disease: 26 mo
13	64	F	None	2-mo Hx of RUL mass; firm RUL mass; CAT scans: generalized lymphadenopathy, hepatosplenomegaly	SL	Monoclonal B	Excisional Bx; systemic chemotherapy	Asymptomatic	NED: 14 mo
14	63	M	None	6-mo Hx of LUL ptosis; LUL fullness with ptosis; generalized lymphadenopathy, hepatosplenomegaly, IgGλ monoclonal gammopathy; LN Bx: lymphoma	FLC	Monoclonal B	Incisional Bx; local irradiation; systemic chemotherapy	17 mo: generalized lymphadenopathy; systemic chemotherapy	Dead: 29 mo, disseminated lymphoma
15	51	F	None	18-mo Hx of left eye prominence; palpable mass above orbital rim, beneath LLL; CAT scan: mediastinal and retroperitoneal lymphadenopathy	SL	Monoclonal B	Incisional Bx; systemic chemotherapy	CAT scan: decreased lymphadenopathy	Alive with systemic disease: 12 mo
16	67	F	None	4-mo Hx of LLL mass; firm, nontender LLL mass; generalized lymphadenopathy	SL	Monoclonal B	Excisional Bx; local irradiation	CAT scan: abdominal lymphadenopathy; Bx: lymphoma; LN Bx: lymphoma	Dead: 15 mo, disseminated lymphoma
17	70	F	None	4-mo Hx of bilateral LLL and RUL swellings; firm LLL mass and visible RUL mass with globe displacement	IL IL	Monoclonal B	Bilateral excisional Bx; bilateral local irradiation	CAT scan: retroperitoneal lymphadenopathy; LN Bx: lymphoma; BM Bx: lymphoma; systemic chemotherapy	Alive with systemic disease: 24 mo
18	86	F	None	12-mo Hx of RUL swelling and ptosis, LUL and LLL lumps; palpable RUL, LUL, LLL masses with RUL ptosis; bilateral cervical, axillary lymphadenopathy; LN Bx: lymphoma; BM Bx: negative	F + DSC F + DSC	Monoclonal B	Incisional Bx; local irradiation	Asymptomatic	Alive with systemic disease: 24 mo

Abbreviations: RUL, right upper lid; RLL, right lower lid; LUL, left upper lid; LLL, left lower lid; RLH, reactive lymphoid hyperplasia; SL, small lymphocytic lymphoma; IL, intermediate lymphocytic lymphoma; FLC, follicular large cell lymphoma; DLNC, diffuse large, noncleaved cell lymphoma; F + DSC, follicular and diffuse small cleaved cell lymphoma; DPDL, diffuse poorly differentiated lymphocytic lymphoma; Hx, history; Bx, biopsy; LN, lymph node; BM, bone marrow; NED, no evidence of disease; CAT, computed axial tomography.

temic lymphoma, patients with simultaneous bilateral ocular lymphoid neoplasms, and patients who were discovered to have concurrent ocular adnexal and nonocular lymphoid neoplasms at the time of presentation. The results of these studies demonstrate the utility of immunogenotypic analysis in the diagnosis, classification, and investigation of extranodal lymphoid neoplasms.

MATERIALS AND METHODS

Patients. Eighteen patients presenting with an ocular adnexal lymphoid neoplasm were included in this study (Table 1). These patients were randomly selected from among cases of ocular adnexal lymphoid neoplasia that had been previously well characterized and in which adequate numbers of cells were available for Southern blot hybridization analysis.

Specimens. One sample of heparinized peripheral venous blood and representative portions of the surgical biopsy specimens of 20 ocular adnexa and three lymph nodes, all suspected of involvement by malignant lymphoma, were obtained from these 18 patients. These specimens were collected under sterile conditions during the course of standard diagnostic procedures. A mononuclear cell suspension of greater than 95% viability and free of erythrocytes, dead cells, and cellular debris was prepared from each sample by Ficoll-Hypaque (Pharmacia Fine Chemicals, Piscataway, NJ) density gradient centrifugation.[18] Immunophenotypic analysis was performed at the time of mononuclear cell isolation before cryopreservation. Excess cells were cryopreserved in vapor-phase liquid nitrogen at −170°C in the presence of dimethylsulfoxide and fetal calf serum.

Histopathology. Hematoxylin-eosin–stained sections were prepared from the paraffin blocks from each biopsy specimen corresponding to the tissue investigated by immunophenotypic and molecular genetic analysis. Each ocular lymphoid neoplasm was classified as an inflammatory pseudotumor, reactive lymphoid hyperplasia, or malignant lymphoma according to previously established histopathologic criteria.[19] The malignant lymphomas were subclassified according to the working formulation of the non-Hodgkin's lymphomas.[20] All additional relevant biopsy specimens also were reviewed, even though these tissues might not have been subjected to special studies.

Immunophenotypic analysis. The proportion of cells in each pathological sample that formed sheep erythrocyte rosettes, expressed surface Ig (sIg) and/or a variety of B- and T cell–associated differentiation antigens, Ia, B1, B4, Leu-14, T1, T3, T4, and T8,[21] was determined in suspensions of viable mononuclear cells by using previously described techniques.[22]

Molecular genetic analysis. DNA was extracted from each of the 24 pathological samples by standard techniques.[23] Twenty micrograms of DNA was digested with the appropriate restriction endonuclease and analyzed for Ig and Tβ gene rearrangements by Southern blot hybridization.[24] Hybridization was performed in 50% formamide, 3× standard saline citrate buffer (SSC) at 37°C for 16 hours. The filters were washed in 0.2 × SSC and 0.5% sodium dodecyl sulfate, pH 7.0, at 60°C for two hours.[25] DNA clones representative of different portions of the Ig and Tβ gene loci were ^{32}P labeled by nick-translation[26] for use as probes. The range of specific activities obtained with this DNA-labeling technique is 2 to 5×10^8 dpm/μg. We have determined, by DNA dilution experiments, that clonal populations representing 5% of the total DNA may be detected by using nick-translated probes and these hybridization and washing conditions. The IgH gene locus was studied by hybridization of *Eco*RI- and *Hind*III-digested DNA to a J region (J_H)-specific probe, a *Bam*HI-*Hind*III 6-kilobase fragment representative of the entire J_H region (kindly provided by Dr Stanley Korsmeyer, National Institutes of Health).[27,28] The Tβ gene locus was analyzed by hybridization of *Eco*RI- and *Bam*HI-digested DNA to a Tβ gene probe that hybridizes to both constant region alleles (a gift from Dr Tak Mak, Ontario Cancer Institute).[11,29]

RESULTS

Clinical features. The age, sex, pertinent prior history, clinical presentation and findings, histopathologic and immunophenotypic diagnosis, form of therapeutic intervention, subsequent clinical course, and eventual outcome of each of the 18 patients included in this study is summarized in Table 1. The patients ranged from 43 to 86 years of age (mean age, 63 years). Six patients were male, and 12 patients were female. Sixteen patients (Table 1, case nos. 1 to 16) presented with unilateral, and two patients (Table 1, cases 17 and 18) presented with simultaneous bilateral, ocular adnexal lymphoid neoplasms. Both patients with bilateral and five of the 16 patients (Table 1, case nos. 11 to 15) with unilateral, ocular adnexal lymphoid neoplasms were discovered to have disseminated systemic lymphoma at the time of presentation. One of these five patients (Table 1, case no. 11) had a history of generalized lymphadenopathy and carried a prior lymph node biopsy diagnosis of "diffuse, poorly differentiated lymphocytic lymphoma." The remaining 11 patients had no evidence of systemic lymphoma based upon radiological and, in some instances, bone marrow examination at the time of presentation. However, patient no. 1 had undergone an excisional biopsy of a histopathologically benign right upper lid mass 3 years earlier. Systemic evaluation was negative at that time, and therapy had never been initiated. Patient no. 4 had an undocumented history of a "benign lung lymphoma" that had been treated by irradiation.

Immunophenotypic and histopathologic analysis. We performed immunophenotypic analysis on each of the 20 ocular adnexal lymphoid neoplasms occurring in these 18 patients and also on three samples of lymph node and one sample of peripheral blood obtained from three of these 18 patients (Tables 2 and 3). The results of these analyses determined that 15 ocular adnexal lymphoid neoplasms occurring in 13 patients (Table 1, case nos. 6 to 18) were monoclonal B cell proliferations. This includes six patients with unilateral ocular lymphoid neoplasms limited to the ocular adnexa, the two patients with simultaneous bilateral ocular adnexal lymphoid neoplasms, and all five patients discovered to have nonocular lymphoid neoplasia. The unila-

teral ocular adnexal lymphoid neoplasms occurring in the five remaining patients (Table 1, case nos 1 to 5) were polyclonal lymphoid proliferations.

Each of the 15 ocular adnexal monoclonal B cell neoplasms contained $\geq$60% B cells expressing either κ or λ light chains. The immunoglobulin isotype was IgMDκ in 7; IgMκ in three; and IgMDλ, IgMλ, and IgGλ in one case each, respectively. We did not determine the Ig heavy chain class in two cases; one of these cases expressed λ and 1 case expressed κ light chains. The bilateral ocular adnexal lymphoid neoplasms occurring in a single individual expressed an identical Ig isotype. Each nonocular lymphoid neoplasm examined expressed the same Ig isotype as the ocular adnexal monoclonal B cell neoplasm occurring in the same patient.

We classified each of the 15 ocular adnexal monoclonal B cell neoplasms as a malignant lymphoma on the basis of morphological criteria. We subclassified these 15 malignant lymphomas as small lymphocytic,[7] intermediate lymphocytic,[3] diffuse large noncleaved cell,[2] follicular and diffuse small cleaved cell,[2] and follicular large cell.[1] The bilateral ocular adnexal lymphoid neoplasms occurring in a single individual were identical morphologically. In addition, each nonocular lymphoid neoplasm was similar morphologically to the ocular adnexal lymphoid neoplasm occurring in the same patient.

Each of the five ocular adnexal polyclonal lymphoid neoplasms contained an admixture of T and B cells. The proportion of T cells ranged between 44% and 69% on the basis of T1 and/or T3 antigen expression. The T cell population consisted of T4$^+$ and T8$^+$ cells in ratios ranging from 3.2 to 8.6. The B cell population consisted of κ and λ light chain–positive B cells in ratios ranging from 0.5 to 1.6. We interpreted these five ocular adnexal lymphoid neoplasms as reactive lymphoid hyperplasias on the basis of morphologic criteria.

Molecular genetic analysis. We investigated the organization of the IgH and the $T\beta$ gene loci in each of the 20 ocular adnexal lymphoid neoplasms occurring in these 18 patients. Each of the 15 ocular adnexal lymphoid neoplasms that we determined to be a monoclonal B cell proliferation by immunophenotypic analysis exhibited clonal IgH gene rearrangements upon hybridization of *Eco*RI- or *Hind*III-digested DNA to a J_H-specific DNA probe. In addition, the ocular adnexal monoclonal B cell neoplasm occurring in each individual exhibited a unique IgH gene rearrangement pattern consistent with a derivation from a distinctive B cell clone (representative data are illustrated in Fig 1). The bilateral ocular adnexal lymphoid neoplasms occurring simultaneously in each of two individuals (Table 1, case nos. 17 and 18) exhibited identical clonal IgH gene rearrangement patterns (Fig 2), which suggested that they are derived from the identical B cell clone and do not represent separate primary neoplasms.[30] None of these monoclonal B cell neoplasms exhibited clonal $T\beta$ gene rearrangements upon hybridization of *Eco*RI- or *Bam*HI-digested DNA to a $T\beta$ gene DNA probe (data not shown). We had previously demonstrated that approximately 11% of lymphoid neoplasms exhibit both clonal IgH and $T\beta$ gene rearrangements, ie, they are bigenotypic.[28] The absence of bigenotypic neoplasms in this series suggests that extranodal lymphoid neoplasms may be bigenotypic less often than are nodal lymphoid neoplasms.

We also examined one peripheral blood and three lymph node samples obtained from three of the patients discovered to have concurrent ocular adnexal and nonocular lymphoid neoplasia (Table 1, case nos. 14 to 16). We demonstrated by immunophenotypic analysis that each of these samples con-

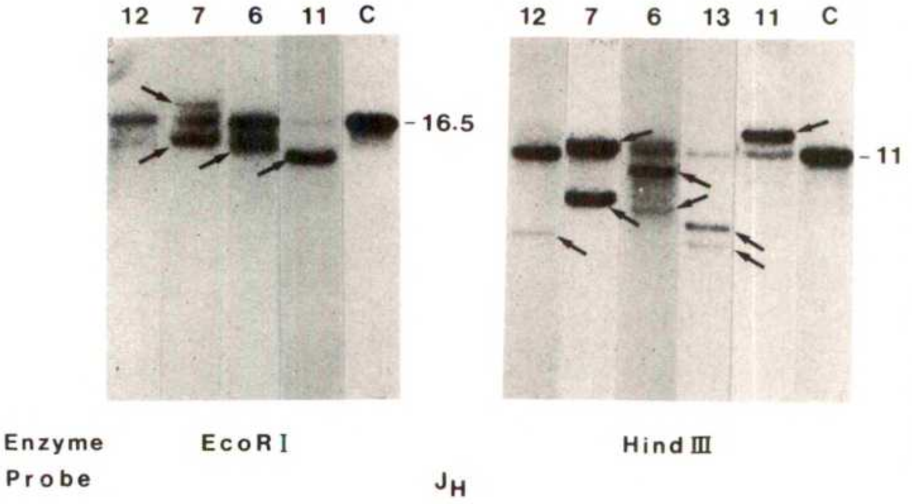

Fig 1. Southern blot hybridization analysis of IgH gene in DNAs extracted from ocular adnexal monoclonal B cell neoplasms. Lanes C contain human fibroblast DNA. The number above each of the other lanes corresponds to the case number in Table 1. The DNAs were digested with *Eco*RI and *Hind*III and hybridized to a joining-region, heavy-chain (J_H) probe. Rearrangement bands are indicated by arrows. Lanes C display the IgH gene germline configuration without rearrangement bands. Each of the 15 ocular adnexal lymphoid neoplasms classified morphologically as a malignant lymphoma and determined to be monoclonal B cell by immunophenotypic analysis exhibited clonal IgH gene rearrangement bands.

tained a monoclonal B cell proliferation expressing the same immunoglobulin isotype as the B cells constituting the patient's ocular adnexal lymphoid neoplasm. Molecular genetic analysis with two different restriction endonucleases, *Eco*RI and *Hind*III, demonstrated that the nonocular lymphoid neoplasms in patients no. 14 and no. 16 exhibited a pattern of clonal IgH gene rearrangement bands that was identical to that expressed by the ocular adnexal lymphoid neoplasms occurring in the same patients (Fig 3). Thus, the ocular adnexal and the nonocular lymphoid neoplasms occurring in these two patients appear to be derived from the same B cell clone and do not represent separate primary lymphoid neoplasms. However, the lymph node obtained from patient no. 15 exhibited a clonal IgH gene rearrangement pattern that was distinct from that of the patient's ocular adnexal lymphoid neoplasm (Fig 3). This case may represent a biclonal B cell lymphoma.[31] None of these nonocular lymphoid neoplasms exhibited clonal Tβ gene rearrangements upon hybridization of *Eco*RI- or *Bam*HI-digested DNA to a Tβ-specific DNA probe.

We had interpreted five unilateral ocular adnexal lymphoid neoplasms (Table 1, case nos. 1 to 5) to be benign, polyclonal pseudolymphomas based upon histopathologic examination and immunophenotypic analysis. None of these five pathological samples exhibited clonal Tβ gene rearrangements upon hybridization of *Eco*RI- or *Bam*HI-digested DNA to a Tβ-specific DNA probe (data not shown). However, two of these five pathological samples (Table 1, case nos. 4 and 5) exhibited clear and easily recognizable clonal IgH gene rearrangement bands upon hybridization of *Eco*RI- or *Hind*III-digested DNAs to a J_H-specific probe (Fig 4). A third sample exhibited a faint nongermline band upon analysis of *Eco*RI-digested DNA and three faint, barely perceptible, IgH gene rearrangement bands upon analysis of *Hind*III-digested DNA, which suggested B cell oligoclonality (Fig 4). The two remaining pathological samples (Table 1, case nos. 1 and 2) exhibited the germline IgH DNA configuration (Fig 4). Thus, three of the five ocular adnexal pseudolymphomas that we investigated contained either oligoclonal or conspicuous mono-

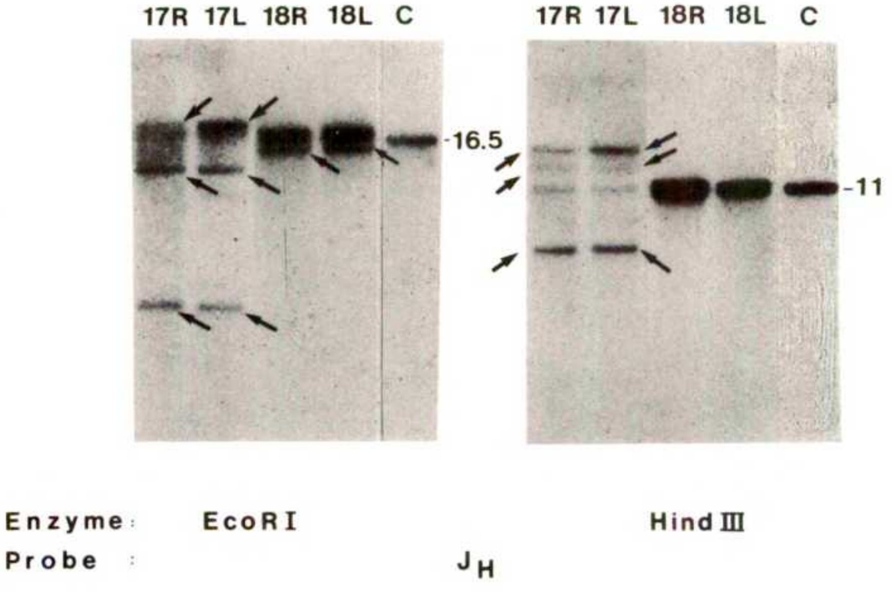

Fig 2. Southern blot hybridization analysis of IgH gene in DNAs extracted from bilateral ocular adnexal monoclonal B cell neoplasms. Lanes C contain human fibroblast DNA. The number above each of the other lanes corresponds to the case number in Table 1, and the letters *R* and *L* indicate right and left, respectively. The DNAs were digested with *Eco*RI and *Hind*III and hybridized to a J_H probe. Rearrangement bands are indicated by arrows. Lanes C show the IgH gene germline configuration without rearrangement bands. The bilateral ocular adnexal monoclonal B cell neoplasms occurring simultaneously in each individual exhibited identical clonal IgH gene rearrangement patterns, which suggested that each neoplasm was derived from the identical B cell clone and that they do not represent separate primary neoplasms.

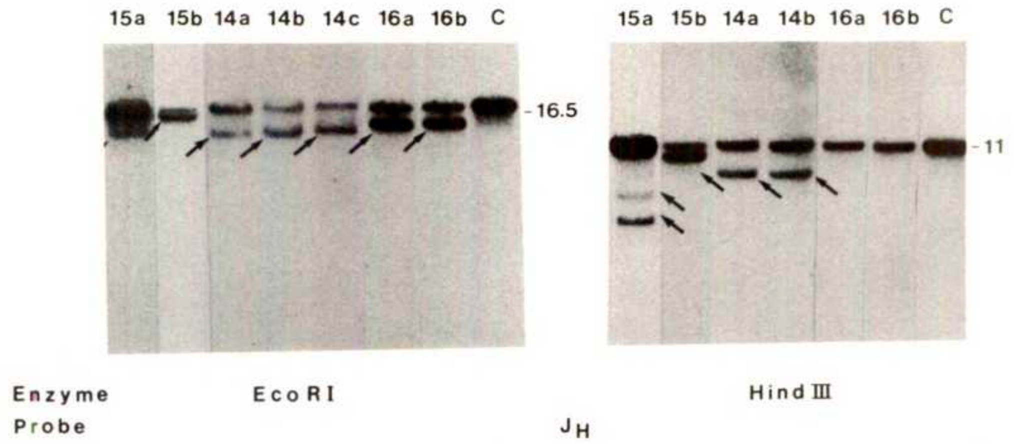

Fig 3. Southern blot hybridization analysis of IgH gene in DNAs extracted from ocular adnexal monoclonal B cell neoplasms and nonocular lymphoid neoplasms occurring concurrently in the same individual. Lanes C contain human fibroblast DNA. The number above each of the other lanes corresponds to the case number in Table 1, and the letters *a*, *b*, and *c* indicate different anatomic sites. The DNA's were digested with *Eco*RI and *Hind*III and hybridized to a J_H probe. Rearrangement bands are indicated by arrows. Lanes C show the IgH gene germline configuration without rearrangement bands. The ocular adnexal and nonocular lymphoid neoplasms occurring concurrently in patient nos. 14 and 16 exhibit identical clonal IgH gene rearrangement patterns which suggested that they are derived from the identical B cell clone. The lymphoid neoplasms occurring in patient no. 15 exhibit distinctive clonal IgH gene rearrangement patterns.

clonal B cell populations by molecular genetic analysis that were not recognizable by morphological examination and immunophenotypic analysis.

Eventual patient outcome. Thirteen of the 18 patients had an ocular adnexal lymphoid neoplasm that we determined to be monoclonal B cell in nature by immunophenotypic analysis. Five of these 13 patients were asymptomatic, without evidence of ocular or nonocular lymphoid neoplasia at 12, 14, 28, 36, and 39 months, respectively. Four patients were alive with evidence of systemic lymphoma at 12, 14, 24, and 26 months, respectively. Three patients died of systemic malignant lymphoma 15, 16, and 29 months after their presentation with an ocular adnexal lymphoid neoplasm. One patient died of metastatic bronchogenic carcinoma 46 months after presentation but had no evidence of ocular or nonocular lymphoid neoplasia at postmortem examination.

Five of the 18 patients had an ocular adnexal lymphoid neoplasm that we determined to be polyclonal by immunophenotypic analysis. The neoplasms in two of these patients were also polyclonal at the molecular genetic level, the

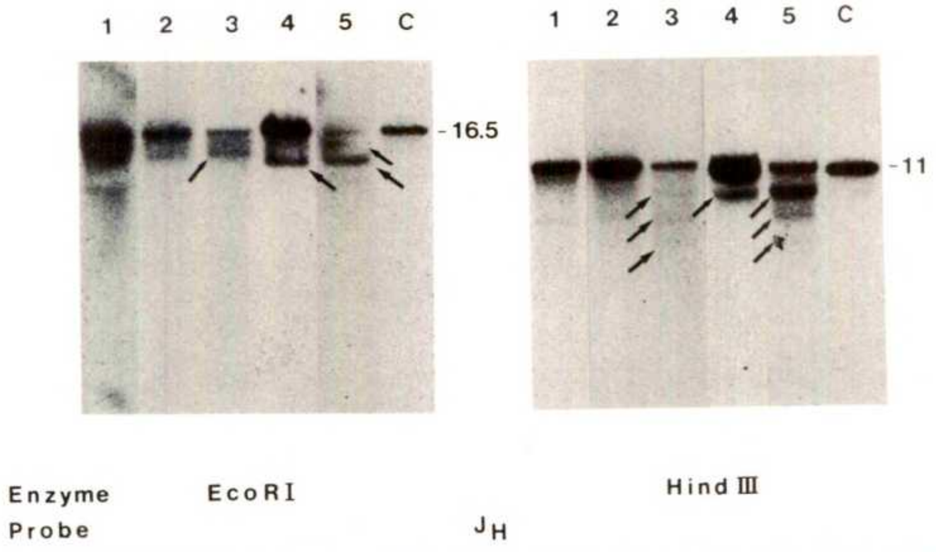

Fig 4. Southern blot hybridization analysis of IgH gene in DNAs extracted from benign, polyclonal ocular adnexal pseudolymphomas. Lanes C contain human fibroblast DNA. The number above each of the other lanes corresponds to the case number in Table 1. The DNAs were digested with *Eco*RI and *Hind*III and hybridized to a J_H probe. Lanes C show the IgH gene germline configuration without rearrangement bands. Case nos. 1 and 2 lack clonal IgH gene rearrangement bands and thus lack detectable monoclonal B cell populations. Case nos. 4 and 5 display clearly visible clonal IgH gene rearrangement bands, which indicate the presence of monoclonal B cell populations. Case no. 3 contains faint, barely perceptible IgH gene rearrangement bands, which suggests the presence of multiple clonal B cell expansions. The clonal B cell populations in case nos. 3 to 5 were not detectable by morphological examination and immunophenotypic analysis.

neoplasm in one patient contained faint oligoclonal bands, and the neoplasms in the two remaining patients contained clearly identifiable clonal B cell expansions by molecular genetic analysis. The two patients with ocular adnexal lymphoid neoplasms that were immunophenotypically polyclonal but monoclonal B cell by molecular genetic analysis were alive, asymptomatic, and without evidence of ocular or extraocular lymphoid neoplasia at 29 and 44 months, respectively. The patient with oligoclonal bands had no evidence of systemic disease after 56 months of follow-up. One of the two patients with a polyclonal lymphoid proliferation was alive and well without evidence of disease at 43 months, whereas the other patient developed a monoclonal B cell proliferation in the contralateral orbit 43 months after the initial presentation.

DISCUSSION

Southern blot hybridization analysis using specific Ig and Tβ gene DNA probes allowed us to determine the lineage and clonality of 20 extranodal lymphoid neoplasms originating and/or presenting in the ocular adnexa of 18 patients and four nonocular lymphoid neoplasms occurring in three of these same patients. The results of molecular genetic analysis were correlated with the results of morphological and immunophenotypic examination of the same samples and with the clinical course of each patient. The results of these studies provide several observations with significant clinical and biologic implications concerning extranodal lymphoid neoplasia. First, ocular adnexal lymphoid neoplasms composed of monomorphic collections of small cytologically mature appearing lymphocytes exhibiting Ig light-chain isotypic exclusion clearly represent clonal B cell expansions. This is true for lymphoid neoplasms originating in and remaining limited to the ocular adnexa as well as those associated with disseminated systemic lymphoma. Second, simultaneous bilateral ocular adnexal monoclonal B cell neoplasms may be derived from the identical B cell clone and do not necessarily represent separate primary tumors. Third, the ocular adnexal and nonocular lymphoid neoplasms occurring concurrently in the same individual may be derived from the same B cell clone. Fourth, many ocular adnexal lymphoid neoplasms currently classified as benign pseudolymphomas may contain clonal B cell expansions demonstrable by molecular genetic analysis, which are not recognizable by histopathologic and/or by immunophenotypic examination. This finding does not necessarily imply that these pseudolymphomas are in reality malignant lymphomas because clonality cannot be equated with malignancy. However, this finding does support the contention that monoclonal B cell lymphomas may arise in extranodal polyclonal pseudolymphomas.

The determination of the benignancy or malignancy of an extranodal lymphoid neoplasm has been based upon traditional, long-established morphological criteria.[32,33] It is generally accepted that cellular polymorphism and cytological maturity favor benignancy whereas monomorphism and cytological atypia favor malignancy.[3] Extranodal small lymphocytic neoplasms have been traditionally classified as benign pseudolymphomas because of their apparent cytological maturity and lack of atypia by morphological examination.[32,33] However, many extranodal small lymphocytic neoplasms resemble nodal small (well-differentiated) lymphocytic lymphomas morphologically.[3] Moreover, the cells frequently express low-density monotypic sIg and the T1 antigen,[5,34] similar to the cells of nodal small (well-differentiated) lymphocytic lymphomas.[35-37] These observations have led some observers to suggest that many extranodal small lymphocytic neoplasms actually represent small (well-differentiated) lymphocytic lymphomas.[2]

Molecular genetic analysis is a considerably more objective and accurate approach than morphological examination and immunophenotypic analysis in determining the lineage and clonality of lymphoid populations. Our molecular genetic studies demonstrate that lymphoid neoplasms resembling nodal small (well-differentiated) lymphocytic lymphomas morphologically and immunophenotypically but that are localized to the ocular adnexa exhibit clonal IgH gene rearrangements. These studies also demonstrate that the various ocular adnexal and nonocular lymphoid neoplasms resembling nodal small (well-differentiated) lymphocytic lymphomas morphologically and immunophenotypically that occur as simultaneous bilateral ocular adnexal or concurrent ocular and nonocular lymphoid neoplasias in a single patient nearly always express an identical pattern of clonal IgH gene rearrangements, which suggests that they are derived from one distinctive B cell clone. This is strong and compelling evidence that the multiple lymphoid tumors exhibiting the small (well differentiated) lymphocytic lymphoma morphology occurring in each individual represent one malignant lymphoma that disseminated. These findings support our contention that extranodal lymphoid neoplasms morphologically identical to nodal small (well-differentiated) lymphocytic lymphoma legitimately fall into the spectrum of small (well-differentiated) lymphocytic lymphomas. Taken together, the clinical, morphological, immunophenotypic, and now the molecular genetic evidence suggests that small lymphocytic neoplasms that occur in extranodal sites such as the ocular adnexa represent the extranodal counterpart of nodal small (well-differentiated) lymphocytic lymphomas whether they are localized to an extranodal site or are disseminated.

It can be correctly argued that the molecular genetic determination of B cell clonality does not in itself imply malignancy, ie, complete transformation, nor does it necessarily imply that a lymphoid neoplasm will behave in a clinically aggressive manner. Nodal small (well-differentiated) lymphocytic lymphomas consistently exhibit clonal IgH gene rearrangements, but they are often clinically indolent and only slowly progressive.[38] The results of the studies presented here suggest that the majority of ocular adnexal small lymphocytic lymphomas remain limited to the ocular adnexa and also are clinically indolent; only a minority are associated with disseminated systemic lymphoma. The ability to predict which small lymphocytic lymphomas will be clinically aggressive may have to await recognition of oncogenic marker(s) associated with their malignant transformation.

It is well known that benign pseudolymphomas occur in each of the anatomic sites in which malignant B cell lymphomas also originate.[1] For example, chronic lymphocytic thyroiditis is commonly seen in association with malignant lymphomas that originate in the thyroid gland.[39] In addition, Sjögren's syndrome and benign lymphoepithelial lesions often antedate the development of monoclonal B cell lymphomas in the salivary glands.[40] Therefore, it has been suggested that extranodal benign pseudolymphomas may serve as precursor lesions and/or be associated with the development of extranodal malignant lymphoma in some instances.[41] Support for this hypothesis comes from the recognition of "clonal proliferation centers" within benign lymphoepithelial lesions of the salivary gland.[42]

In this respect, one of the most interesting observations of this study was that many ocular adnexal lymphoid neoplasms classified as benign pseudolymphomas may contain clonal B cell expansions that are not recognizable morphologically and/or immunophenotypically. In fact, only two of the five ocular adnexal pseudolymphomas that we investigated lacked clonal B cell populations and were truly polyclonal. These results strongly suggest that clonal B cell expansions may commonly occur within benign extranodal pseudolymphomas. This finding provides considerable further support for the contention that monoclonal B cell lymphomas may originate in benign extraodal pseudolymphomas. However, longitudinal multiparametric studies of patients with extranodal lymphoid neoplasms are necessary to substantiate this hypothesis.

It could be argued that we did not identify these small clonal B cell populations immunophenotypically because they were selectively lost during their extraction from the tissue samples. However, our cell isolation techniques have been successfully used in the phenotypic identification of clonal B cell populations for several years and are carefully monitored at each step to avoid cell loss. Mononuclear cell viability was consistently $\geq 90\%$, and appreciable cell loss was not noted in any of the cases included in this study. Moreover, molecular genetic analysis of 45 benign, hyperplastic lymph nodes handled in an analogous manner revealed an occult clonal B cell population in only one instance (data not shown). Therefore, we do not believe that the discrepancy between morphological examination, immunophenotypic analysis, and molecular genetic determination of clonality resides at the technical level. Rather, we believe that the molecular genetic detection of these B cell clones is due to the exquisite sensitivity of the Southern blot technique, which previously has been shown to detect DNA that is representative of $\leq 5\%$ of the total DNA in a given sample.[10,13]

We previously reported that ocular adnexal pseudolymphomas commonly contain increased numbers of T4 antigen–positive T cells.[43] We previously had not been able to determine the clonality of this cell population because there is no reliable phenotypic marker to determine T cell clonality. However, we were now able to investigate the clonality of this T cell population by using a specific DNA probe that detects clonal $T\beta$ gene rearrangements. Using this approach, we demonstrated that the large number of T cells present in some ocular adnexal lymphoid neoplasms do not exhibit clonal $T\beta$ gene rearrangements and therefore do not represent clonal T cell proliferations.

It should be clear from the studies presented here that molecular genetic analysis provides a useful, accurate, and objective approach to evaluate the lineage and clonality of extranodal lymphoid neoplasms. This approach should be useful in identifying patients with extranodal monclonal B cell proliferations that cannot be identified by morphological examination and/or by immunophenotypic analysis and that have been designated indeterminate by some investigators.[44] For example, immunogenotypic analysis should be particularly helpful in examining small biopsy samples of extranodal lymphoid proliferations, specimens in which a large inflammatory response masks a malignant lymphoma, and specimens in which there is only partial involvement by malignant lymphoma. This approach will also be useful in determining clonality in extranodal lymphomas that exhibit atypical histopathology, ie, contain prominent germinal centers, a polymorphous cellular component, or cells that are cytologically mature. The identification of patients with extranodal monoclonal B cell proliferations should provide useful prognostic information and may be helpful in identifying patients in which there is a possibility of conversion from a small (well-differentiated) lymphocytic lymphoma to a diffuse aggressive lymphoma. Furthermore, the identification of a clonal B cell population by its distinctive pattern of Ig gene rearrangements provides a useful genetic marker with which to follow a patient's future lymphoid proliferations.

However, our demonstration of the presence of clonal B cell populations in some morphologically benign and immunophenotypically polyclonal pseudolymphomas also raises important clinical questions concerning the role of antigen receptor gene rearrangement analysis in the diagnosis of malignant lymphoid neoplasia. None of the three patients in this series carrying such lesions developed overt clinical evidence of lymphoid malignancy at 29, 44, and 56 months. We have previously also identified patients with the acquired immunodeficiency syndrome–related complex without clinical evidence of lymphoid malignancy who have hyperplastic lymph nodes containing clonal B cell expansions demonstrable by Southern blot hybridization analysis.[45] These results support a widespread belief that clonality should not be equated with malignancy. It will be necessary to investigate additional cases of extranodal pseudolymphoma and to carefully monitor such patients longitudinally to determine the clinical and biologic significance of these subclincial clonal B cell populations. Nonetheless, the results of these studies demonstrate the value of Southern blot hybridization analysis for clonal Ig and $T\beta$ gene rearrangements in the diagnosis, classification, and investigation of extranodal lymphoid neoplasms originating and/or presenting in the ocular adnexa.

ACKNOWLEDGMENT

The authors express their sincere gratitude to Drs Lois McNally and Evan Sachs for their assistance in portions of these studies; Laurie McFall, Angela Ubriaco, and Dr Bang-Ying Zhu for their technical expertise; and Margaret Walden for careful preparation of the manuscript.

Soluble Interleukin-2 Receptors in the Sera of Patients With Hairy Cell Leukemia: Relationship With the Effect of Recombinant α-Interferon Therapy on Clinical Parameters and Natural Killer In Vitro Activity

By M. Chilosi, G. Semenzato, G. Cetto, A. Ambrosetti, L. Fiore-Donati, G. Perona, G. Berton, M. Lestani, A. Scarpa, C. Agostini, L. Trentin, R. Zambello, M. Masciarelli, F. Dazzi, F. Vinante, F. Caligaris-Cappio, and G. Pizzolo

In this study we provide evidence that the sera of patients with hairy cell leukemia (HCL) contain a factor that can prevent the binding of a monoclonal antibody specific for interleukin-2 receptor (IL-2R) to its target. This factor corresponds to the soluble form of IL-2R (sIL-2R), as assessed by a specific enzyme-linked immunosorbent assay test, and appears to be released by neoplastic hairy cells. The serum sIL-2R levels were very high at diagnosis and significantly reduced during recombinant α-interferon (rIFNα2) therapy. Values of sIL-2R appeared to be inversely related to the natural killer in vitro function displayed by peripheral blood mononuclear cells from the same patients. The presence of sIL-2R in the serum of patients with HCL might be involved in the impairment of cell-mediated immunity observed in these patients and could represent a valuable marker for monitoring different phases of the disease and for modulating IFN therapy.

HAIRY CELL LEUKEMIA (HCL) is a chronic lymphoproliferative disorder characterized by splenomegaly and pancytopenia. The bone marrow is infiltrated by atypical cells showing a peculiar hairy morphology that can usually be found also in the peripheral blood in variable numbers.[1,2] Hairy cells (HC) belong to the B cell lineage and characteristically express the interleukin-2 receptor (IL-2R) on their membranes.[3] This molecule plays a crucial role in lymphocyte proliferation and is normally expressed on the surface of activated T and B cells.[4] It has been recently demonstrated in both human and experimental animals that in vitro activated normal lymphoid cells can release a soluble form of IL-2R (sIL-2R).[5-7]

Contrasting data have been provided on the role of IL-2 in the proliferation of HC in vitro.[3,8] There are some data suggesting the possibility that impairment of the IL-2/IL-2R mechanism might be related to immunologic abnormalities observed in other lymphoproliferative disorders.[9,10]

A severe impairment of natural killer (NK) activity has been extensively demonstrated in HCL.[11-16] The defect of cytotoxic function could contribute to the increase susceptibility of HCL patients to infections, which represent the primary cause of mortality in this disease.[17,18] One interesting possibility in HCL is that the IL-2R might adsorb and block IL-2, thereby making it unavailable for stimulating NK cells.[19] Such a mechanism would be greatly facilitated by the release of sIL-2R from HC and its diffusion through the plasma and internal milieu. To test this hypothesis, we looked for the presence of sIL-2R in the sera of patients with HCL by using two different techniques: a competitive binding immunocytochemical assay and a recently standardized enzyme-linked immunosorbent assay (ELISA) test. We tested eight patients with HCL at diagnosis and during their clinical and hematologic improvement after therapy with α-interferon (rIFNα2), which is highly effective in HCL.[20] The findings have been compared with the analysis of NK cell in vitro function.

MATERIALS AND METHODS

Patients and sera. Eight patients with HCL, one female and seven males (average age, 62 years, Table 1), were studied. The main clinical and laboratory data of patients at diagnosis and their variations during rIFNα2 therapy are shown in Fig 1. The diagnosis of HCL was based on clinical, morphological, cytochemical, and immunophenotypic criteria.[1-3] In all patients bone marrow involvement was confirmed by the immunohistochemical demonstration of HC.[21] All patients had severe neutropenia ($<0.5 \times 10^9$/L) and entered a therapeutic protocol with rIFNα2 (Schering Corp, Kenilworth, NJ). None of the patients had splenectomy nor underwent any other treatment before rIFNα2 therapy. Treatment started in November 1984 for the first three patients, whereas the other patients started the therapeutic regimen later. The protocol consisted of 2×10^6 IU/m^2 of rIFNα2 injected subcutaneously three times a week for 12 months. Informed consent was obtained from all patients, who had been advised of procedures and attendant risks. Samples of serum were collected from all patients at diagnosis and at different times during rIFNα2 therapy and evaluated for the presence of sIL-2R in conjunction with clinical and phenotypical assessment of the disease status. Sera from 40 normal age-matched subjects were used as control.

Competitive binding immunocytochemical assay to detect sIL-2R. The exquisitely sensitive alkaline phosphatase anti–alkaline phosphatase (APAAP) technique[22] was used to detect the specific immunostaining of anti–IL-2R+ target cells and reveal the inhibitory capability of sera. Hightly enriched T cells obtained by E rosetting sedimentation from the peripheral blood mononuclear cells (PBMC) of normal donors were activated in vitro for 72 hours with 2 μg/mL Phytohaemagglutinin (PHA-M) (Difco Detroit) and used as standard IL-2R+ targets. The anti–IL-2R monoclonal antibody (MoAb) was purchased from Becton Dickinson, Sunnyvale, CA (lot no. H0716).

Table 1. Semiquantitative Evaluation of the Inhibitory Capability of Patients' Sera on the Binding of Anti–IL-2R Antibody to Activated T Cells

Patient No.	Age	Sex	Dilutions of Patient's Serum 1:1	1:2	1:5	1:10*
1	44	M	+	+	+	−
2	64	F	+	+	+	−
3	64	M	+	+	−	−
4	70	M	+	+	+	−
5	75	M	+	+	+	−
6	57	M	+	+	+	−
7	71	M	+	+	−	−
8	57	M	+	+	+	+
Normal (ten cases)			−	−	−	−

Patients' sera were obtained at diagnosis. + complete inhibition of anti-IL2R binding to activated T cells.

*One microliter anti–IL-2R antibody (1:100 dilution) was mixed with different volumes of patient's serum (1 μL, 2 μL, 5 μL, 10 μL), the final volume adjusted to 10 μL with PBS.

Anti–IL-2R antibody was first diluted 1:100 in phosphate-buffered saline (PBS). One microliter of this solution was then added to 10 μL PBS (obtaining the 1:1,000 final working dilution used to detect positive staining) or to 10 μL of sera at different dilutions (1:1, 1:2, 1:5, 1:10, 1:20). The mixtures containing antibody and sera were allowed to incubate for 20 minutes at room temperature before the immunocytochemical staining.

Acetone-fixed cytocentrifuged preparations of activated T cells were incubated for 30 minutes with anti–IL-2R antibody diluted 1:1,000 in PBS or serum at various dilutions. After washing, the preparations were reacted for 30 minutes with a goat antimouse Ig "bridge" antibody before the incubation with the APAAP complex (purchased from Dako, Copenhagen). Finally, alkaline phosphatase was revealed cytochemically by means of naphthol AS-BI phosphate (Sigma Chemical Co, St Louis) as the substrate and hexazotized neufuchsin (Serva, Heidelberg, FRG) as the chromogen.

The immunostained preparations were evaluated as positive or negative by direct microscope observation and semiquantitative scoring of the number of IL-2R+ cells in the preparations. Preparations were considered negative when less than 1% of the cells showed a faint positivity.

Additional IL-2R+ targets were cryostat sections of HCL bone marrow trephine biopsy material and samples of Hodgkin's disease–involved lymph nodes. Both presented large numbers of IL-2R+ cells, HC, and Reed-Sternberg cells,[23] respectively.

Controls. Three different types of controls were performed. First, the possible inhibition of binding of MoAbs other than anti–IL-2R (Leu-4, Leu-1, and anti–HLA-DR, from Becton Dickinson) by normal and patient's sera was investigated in parallel tests. The antibodies used as controls were either of the same class as anti–IL-2R (IgGl, Leu-4) or of different classes (IgG2a, anti–HLA-DR and Leu-1)

Second, the possibility that the preincubation of target cells with the sera could prevent the binding of anti–IL-2R antibody was checked to rule out the presence in HCL sera of autoantibodies specific for IL-2R, as found in systemic lupus erythematosus.[24] These antibodies could produce similar inhibition of anti–IL-2R binding to target cells in the same system. Finally, the sera were dialyzed overnight in buffered saline by using standard Visking tubes before testing for immunocytochemical inhibition.

ELISA test for the determination of sIL-2R. Two MoAbs recognizing different epitopes of the IL-2R molecule were used in an ELISA test (Cellfree, T Cell Science, Cambridge, MA). Briefly, sIL-2R available in the samples or standards bind to the polystyrene microtiter wells previously incubated with 100 μL anti–IL-2R MoAb (1 μg/mL). A horseradish peroxidase–conjugated anti–IL-2R MoAb directed against a second epitope on the IL-2R molecule binds to the IL-2R captured by the first antibody and completes the sandwich. After washing to remove the unbound enzyme-conjugated anti–IL-2R MoAb, a substrate solution is added to the wells. The reaction is then stopped and the absorbance determined at 490 nm. A standard curve was prepared by using different sIL-2R concentrations defined in arbitrary units per milliliter (considering 1,000 U/mL the amount of sIL-2R present in 0.1 mL of a T Cell Science reference preparation of supernatant from phytohemagglutinin-stimulated lymphocytes).

Demonstration of sIL-2R release by HC in vitro. HC-enriched populations were obtained in five patients in which, at the time of diagnosis, the frequency of HC was highest. HC-enriched cell suspensions were obtained after removal of T cells according to the method previously described in detail[25] and never contained >1% T cells or monocytes as detected by indirect immunofluorescence with CD3 MoAb and α-naphthyl acetate esterase. The frequency of anti-Tac and tartrate-resistant acid phosphatase–positive cells was >77% and >86%, respectively.

The HC-enriched populations (1×10^4/well) were cultivated in RPMI 1640 supplemented with 10% fetal calf serum (FCS, Microbiological Products, Wakersville, MA), penicillin, streptomycin, and L-glutamine in 96-well U-bottomed microtiter plates in a final volume of 200 μL. They were cultured for three or seven days in a 5% CO_2 atmosphere in the presence of medium alone or 12-0-tetradecanoylphorbol-13-acetate (TPA 10 ng/mL/1×10^6 cells; Sigma) and/or B cell growth factor (BCGF, 20% vol/vol 1×10^6 cells; Chemicon, El Segundo, CA). All cultures were performed in triplicate. After the incubation period, the plates were centrifuged, and culture supernatants were harvested to determine the presence of sIL-2R as described earlier. Cellular viability was always >95%.

Evaluation of NK activity. PBMC were obtained from freshly drawn heparinized peripheral blood by centrifugation on a Ficoll/Hypaque gradient. The cells were washed three times and resuspended in RPMI 1640. Adherent cells were removed by two sequential incubations in plastic Petri dishes for 45 minutes at 37°C in an atmosphere of 95% air and 5% CO_2.

NK activity was assessed by lysis of ^{51}Cr-labeled K-562 target cells as previously described.[15] Briefly, target cells were labeled overnight at 37°C in 5% CO_2 with 100 μCi Na $^{51}CrO_4$ (CEA, Saluggia, Italy; IRE Sorin, Biomedica), extensively washed three times before use, and then adjusted to a final concentration of 10^5 cells/mL in RPMI 1640 supplemented with 10% FCS. To perform the test, 100 μL labeled targets (10^4 cells) was cocultured with effector cells for four hours at 37°C in 5% CO_2 at different dilutions to final ratios between effectors and target cells (E/T) of 5:1, 10:1, 20:1, 40:1, and 80:1 in triplicate round-bottomed wells (Limbro Scientific Co, Hamden, CT). Triplicate wells with target cells in medium alone and in detergent were assessed to determine spontaneous and maximum release, respectively. After this incubation, supernatants were harvested and counted in a gamma counter. The mean value of triplicate assays was used to calculate the percentage of cytotoxicity according to the following formula: percent cytotoxicity = (cpm release in test − cpm spontaneous release) × 100/(cpm maximum release − cpm spontaneous release). Spontaneous release from the target cells was always <8%. Nonadherent PBMC from 20 age-matched healthy volunteers were used as control. Data are presented at the standard 80:1 E/T ratio as previously described in detail.[15]

NK cell activity after in vitro incubation with IL-2. The effect of IL-2 on the cytotoxic activity was determined after in vitro boosting. Effector cells (1×10^6/mL) were cultured in RPMI 1640

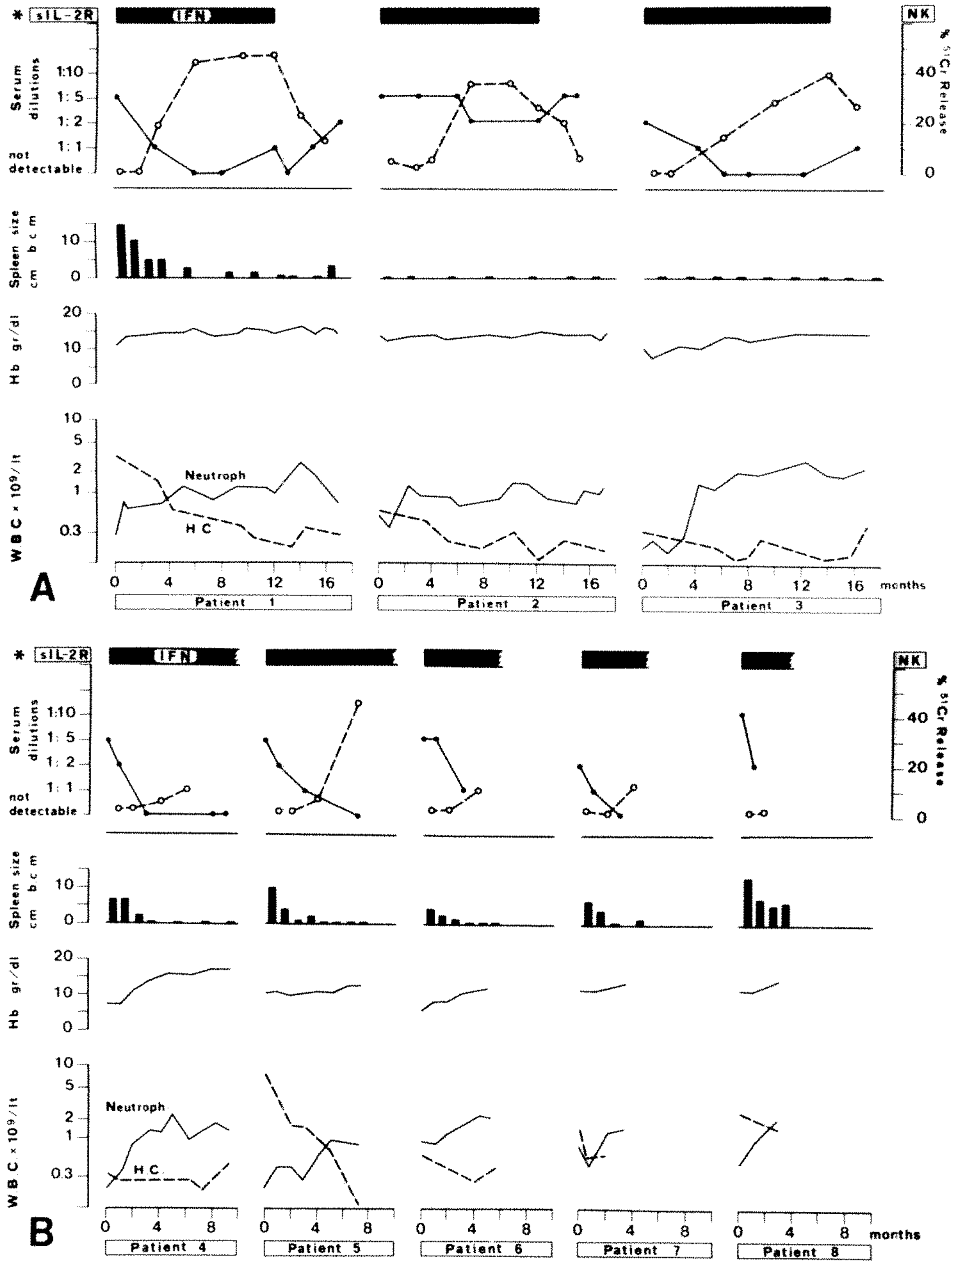

Fig 1. (A) Longitudinal evaluation of clinicohematologic data in relationship with sIL-2R (—●—) levels and NK activity (—O—) of patients with HCL treated with rIFNα2 (case nos. 1, 2, and 3). *Inhibitory capability of HCL sera on the binding of anti–IL-2R antibody to activated T cells (sIL-2R) expressed as maximal serum dilutions at which sIL-2R is detectable. (B) Longitudinal evaluation of clinicohematologic data in relationship with sIL-2R (—●—) levels and NK activity (—O—) of patients with HCL treated with rIFNα2 (cases 4 to 8). *Inhibitory capability of HCL sera on the binding of anti–IL-2R antibody to activated T cells (sIL-2R) expressed as maximal serum dilutions at which sIL-2R is detectable.

medium supplemented with 10% FCS, 4 mmol/L glutamine, penicillin (100 U/mL), and streptomycin (50 mg/mL) and that contained 20% vol/vol lectin-free IL-2 (Lymphocult-LF, Biotest, Frankfurt, FRG) for 72 hours at 37°C in a 5% CO_2 atmosphere. After incubation with IL-2, the cells were washed, resuspended in fresh medium, and immediately tested for cytotoxicity as described earlier. These doses and times were previously found to give the highest increase of NK activity on normal peripheral blood lymphocytes (data not shown). In all experiments effector cells cultured in the same conditions, but without IL-2, were used as controls. To rule out the possibility of a stimulatory effect of the FCS present in the culture medium, appropriate controls with medium alone were performed. In these experiments no appreciable cytotoxic activity was detected. Results are expressed as percentages of ^{51}Cr release (at the 80:1 E/T ratio) by cells cultured with IL-2 with respect to the cells cultured in the same experimental conditions but without IL-2.

RESULTS

When cytospin preparations of activated T cells were stained with anti–IL-2R antibody at a 1:1,000 dilution, the APAAP technique revealed membrane staining in 25% to 50% of the cells. The reactivity was not inhibited by normal sera (ten cases) added in the highest concentrations used in our system (1 μL prediluted anti–IL-2R antibody plus 10 μL serum; final concentration, 1:1,000). On the other hand, all the sera of HCL patients at diagnosis completely inhibited the anti–IL-2R staining (Table 1). The inhibition was seen at 1:1, 1:2, and 1:5 dilutions, and a positive staining appeared again only when anti–IL-2R antibody was mixed with HCL sera at the highest dilutions. Most cases (5/8) showed inhibitory capability at a 1:5 serum dilution, one case at 1:10, and two cases at 1:2 (Table 1).

Table 2. Quantitative Evaluation of sIL-2R in the Sera of HCL Patients at the Time of Diagnosis and During rIFNα2 Therapy

†Months after the beginning of rIFNα2 therapy.

Controls. The sera of patients with HCL did not inhibit the immunostaining of MoAbs other than anti–IL-2R (anti–HLA-DR, Leu-4, and Leu-1) in an identical system using the same (1:1,000) antibody dilution. The binding of anti–IL-2R antibody was not prevented by preincubation of activated T cells with the sera of patients affected with HCL. Overnight dialysis of sera did not modify their inhibitory capability.

ELISA test for the determination of sIL-2R. The presence of sIL-2R in the sera of HCL patients at diagnosis was confirmed by using the enzyme immunoassay (Table 2). In all cases the values were very high (mean ± SD = 25,858 ± 11,846 U/mL; range, 13,370 to 48,090 U/mL) when compared with those observed in age-matched normal controls (mean ± SD = 232 ± 118 U/mL; range, 75 to 496 U/mL).

Detectable levels of sIL-2R were found to be released in the supernatants of cultured HC after stimulation up to seven days. sIL-2R were undetectable in all cases at day 0, ranged between 73 and 1,300 U/mL at day 3, and between 132 and 2,600 U/mL at day 7. Spontaneous sIL-2R release was documented without stimulation in two cases.

sIL-2R serum levels after rIFNα2 therapy. A consistent reduction of sIL-2R levels was observed after rIFNα2 therapy. This was demonstrated by the decrease and eventually the disappearance of the inhibitory effect of sera in the cytochemical competitive assay (Fig 1) as well as by the progressive reduction of values obtained with the ELISA test (Table 2). sIL-2R levels started to rise again after discontinuation of the rIFNα2 therapy as shown in the patients with the longest follow-up (Fig 1 and Table 2). In only one patient who received rIFNα2 for 1 year (case no. 2) were the sIL-2R levels only partially reduced during the course of therapy. This same patient experienced a rather modest clinical response (only a moderate increase of granulocytes and a small reduction of HC levels in the bone marrow). In the other patients the progressive loss of sIL-2R in the serum correlated with clinical improvement, as judged by the decrease of neoplastic cells in peripheral blood and marrow, the reduction of the spleen size in patients with enlarged spleens, and the increase in granulocytes and hemoglobin levels (Fig 1).

Relationship between sIL-2R levels and NK in vitro activity. As shown in Fig 1, the NK in vitro function was severely impaired before therapy in our patients. The cytotoxic ability of patients' mononuclear cells started to increase in the third month of rIFNα2 therapy and reached normal values after 6 months. In the three patients who had already discontinued therapy, rIFNα2 interruption was followed by a new decrease in NK function (Fig 1). Interestingly, the NK function in the HCL patients appeared inversely related to the levels of sIL-2R (Fig 1). Notably, when the sIL-2R levels were high, the NK function was low; when the sIL-2R levels reached their nadir, the cytotoxic ability began to increase.

In vitro effect of IL-2 on NK activity. The stimulatory effect of exogenous IL-2 on the NK in vitro function of PBMC from HCL patients is shown in Table 3. At the time of diagnosis before any treatment, exogenous IL-2 was able to provide a dramatic increase in the cytotoxic in vitro function in all tested patients. It is worth mentioning that at this time the highest levels of sIL-2R were also observed in the patients' serum.

After a 6-month period of therapy with rIFNα2 when sIL-2R levels were significantly decreased, the NK in vitro function was only slightly susceptible to further increase upon IL-2 stimulation in all cases but one (case no. 2). This pattern was similar to that observed in normal subjects.

The immunophenotypic evaluation of NK-related cells when using Leu-7 and Leu-11 MoAbs showed comparable figures at diagnosis and after 6 months of rIFNα2 therapy (Leu-7, 0.311 × 10^9/L ± 0.169 *v* 0.237 × 10^9/L ± 0.207; Leu-11, 0.127 × 10^9/L ± 0.089 *v* 0.107 × 10^9/L ± 0.071)

Table 3. In Vitro Effect of IL-2 on the NK Activity of PBMC From HCL Patients Before and During rIFNα2 Treatment

	Before Treatment			After 6 mo of Therapy		
	^{51}Cr Release (%)			^{51}Cr Release (%)		
Patient No.	Baseline Value	After IL-2 Activation	Variance	Baseline Value	After IL-2 Activation	Variance
2	5.6	36.0	30.4	21.8	48.8	27.0
3	6.8	39.5	32.7	17.3	21.6	4.3
4	3.7	25.2	21.5	12.0	12.0	0
5	8.0	57.3	49.3	42.5	50.7	8.2
Controls (n = 5)						
	44.6 ± 8.6*	57.7 ± 6.4*	13.1			

For NK activity, a standard assay was performed at an 80:1 E/T ratio.

*SD.

(mean ± SD). This finding suggests that the variations in NK activity are not primarily produced by fluctuations in NK cell numbers.

DISCUSSION

In this paper we provide evidence that the serum of patients with HCL contains high levels of sIL-2R. This was suggested by the selective inhibition of anti–IL-2R antibody binding to activated T cells that was exerted by patients' sera and confirmed by a specific ELISA test. The inhibitory factor corresponding to the sIL-2R should be released in vivo by HC, as suggested by experiments performed in vitro. T cells have been demonstrated to secrete sIL-2R after activation in vitro[5] and might then represent an alternative or supplementary source of sIL-2R in vivo in our patients. Nevertheless, no evidence has been reported of increased T cell activation in HCL. In addition, the sIL-2R levels rarely exceed 2,000 to 4,000 U/mL in other diseases where T cell activation is commonly present such as viral hepatitis, infectious mononucleosis, sarcoidosis, and Hodgkin's disease.[26,27]

Using both methods we could demonstrate that the sIL-2R levels in our patients' sera dramatically decreased after a few months of rIFNα2 therapy. In most patients the decrease in sIL-2R levels corresponded to the clinical recovery and the improvement of erythromyelopoiesis. However, a small number of residual HC could be detected in the bone marrow of all patients, even at the maximum therapeutic effect of rIFNα2 (data not shown), which could account for the observed lack of complete normalization of sIL-2R levels in peripheral blood (Table 2). In addition, the levels of sIL-2R in the serum of HCL patients and the NK in vitro function of PBMC appeared inversely related.

These findings have a series of relevant implications. First, the observed impairment of cell-mediated immunity in HCL[17,18] might be correlated with the overproduction and accumulation of sIL-2R in the serum. As a consequence, the excess sIL-2R released in the serum in vivo might bind IL-2 and block the IL-2/IL-2R modulation necessary for effective cellular proliferation.[28,29] This interpretation is supported by the recent report that sIL-2R released by activated T cells maintain the capability of binding IL-2.[30]

The putative defect of IL-2 at serum level may be particularly important for the NK system in HCL patients where a severe impairment of the NK function has been extensively demonstrated.[11-16] Supportive evidence of the relevance of IL-2 in the mechanisms of the impaired cytotoxic response in HCL is provided by the fact that the addition of exogenous IL-2 to short-term cultured PBMC from HCL patients can restore their NK activity (Table 3).[14,15]

The significant increase of NK function observed during IFN therapy and corresponding to the decrease of sIL-2R levels (Fig 1 and Table 2) raise the question of the relationship between IFN therapy and its biologic and clinical effects. The mechanisms involved in the therapeutic actions of IFN on HCL and other neoplasms are still controversial. It is not established whether IFN directly exerts a cytotoxic effect on neoplastic cells, for example, by inhibition of BCGF-induced proliferation of HC.[31] Alternatively, IFN could indirectly reduce the neoplastic mass by increasing the susceptibility of HC via the modulation of membrane antigens, including HLA-DR determinants,[32] or by the stimulation of immunologic defenses (especially the NK system).[33] The observed lack of timing between the restoration of NK activity and HC decrease in treated patients does not support this latter possibility. This is also suggested by the recent data on the absence of cytotoxic activity of NK cells from HCL patients on their own neoplastic cell population.[34] All these findings favor the hypothesis that the increase in cytotoxic activity observed in HCL after α-IFN therapy represents the effect of a nonspecific enhancement of the host immune system.

The only exception in our study was represented by patient no. 2 in whom high serum levels of sIL-2R were detectable during the entire follow-up of the treatment. A limited clinical response was obtained in this patient, but NK activity significantly recovered during rIFNα2 therapy (Fig 1). This discrepancy may be tentatively explained by differences in IL-2–binding capacity of soluble receptors and/or by a direct activation of NK cells by interferons independent of IL-2 availability. This latter possibility, however, is unlikely because exogenous IL-2 also produced a significant stimulation of in vitro NK activity after 6 months of therapy.

All these considerations taken together suggest that the evaluation of sIL-2R in the serum, beside its relevance to the comprehension of immunologic phenomena taking place in HCL, may be important for monitoring the disease and particularly the response of different patients to interferon therapy. Longitudinal studies are now in progress to verify this possibility.

ACKNOWLEDGMENT

The authors wish to thank the Essex Italia (Schering Corp, Kenilworth, NJ) for providing the rIFNα2. We thank Professor G. Janossy, London, for advice and criticism and L. Montagna for her skillful technical assistance.

Synergistic Action of Calcium Ionophore A23187 and Phorbol Ester TPA on B-Chronic Lymphocytic Leukemia Cells

By Hans G. Drexler, Malcolm K. Brenner, Elaine Coustan-Smith, R. Gitendra Wickremasinghe, and A. Victor Hoffbrand

The peripheral blood mononuclear cells from 16 patients with B-chronic lymphocytic leukemia (B-CLL, n = 13), B-prolymphocytic leukemia (B-PLL, n = 2) or hairy cell leukemia (n = 1) were incubated in the presence of the phorbol ester 12-0-tetradecanoylphorbol-13-acetate (TPA) and the calcium ionophore A23187. A synergy between these inducers was found with respect to morphological changes and B cell proliferation and differentiation. A23187 used alone did not activate the cells. B-CLL cells treated with the double stimulus acquired a plasmacytoid morphology, showed significantly higher incorporation of ^{3}H-thymidine and ^{3}H-uridine, and produced significantly higher amounts of monoclonal immunoglobulin compared with the same cells exposed to either of the inducers alone. These results indicate that phorbol ester and calcium ionophore act synergistically on B-CLL cells to induce proliferation and differentiation. B-PLL cells responded more vigorously to the signals provided by TPA and A23187. Previous studies showed that TPA and A23187 can mimic the two physiological second messengers diacylglycerol and inositol trisphosphate in the transduction of signals leading to cell activation, proliferation, and differentiation in normal B cells. The present findings suggest that the capacity of B-CLL and B-PLL cells to differentiate in response to signals of the second messenger pathway is intact.

©1987 by Grune & Stratton, Inc.

CHRONIC LYMPHOCYTIC LEUKEMIA (CLL) is, in most cases, a monoclonal expansion of neoplastic B cells in which differentiation blockage appears to be a basic defect leading to a clonal excess of these cells. Release of this blockage might have therapeutic benefits. Numerous studies have shown that the phorbol ester 12-0-tetradecanoylphorbol-13-acetate (TPA) can stimulate differentiation of B cell CLL (B-CLL) cells in vitro into more mature forms[1] and elicit a variety of biologic responses. TPA-treated cells showed altered cell morphology associated with a more differentiated state,[2] and TPA alone induced the secretion of idiotypically identical immunoglobulin (Ig) and caused characteristic changes in the expression of B cell–associated surface antigens.[3]

Recent studies have provided new insights into the molecular basis of signal transduction triggering cellular activation and proliferation. The key event in this signal transduction pathway is the hydrolysis of membrane-associated inositol phospholipids that leads to the generation of two products that act as second messengers of cell activation. Cell activation is initiated in T cells by interaction between an antigen associated with a major histocompatibility complex (MHC) molecule and the T cell receptor[4] and in B cells by cross-linking of receptor immunoglobulin by antigen or antireceptor antibodies.[5] This receptor-ligand interaction causes the hydrolysis of phosphatidyl inositol bisphosphate located in the cell membrane to diacylglycerol and inositol trisphosphate.[6] These two second messengers trigger two parallel pathways that act in concert. Inositol trisphosphate mediates the mobilization of intracellular free calcium by release of Ca^{2+} from intracellular stores, whereas diacylglycerol directly activates protein kinase C, a key calcium-dependent enzyme in cell activation. The subsequent protein kinase C–mediated protein phosphorylation leads to alterations in ion flux that are manifested in membrane depolarization and an increase of intracellular pH.[4,5] These events seem to be causally related to cellular activation and growth.[4]

The intracellular signals triggered by inositol trisphosphate and diacylglycerol can be independently mimicked by calcium ionophores (such as A23187) and phorbol esters (such as TPA), respectively. A23187 causes Ca^{2+} mobilization (calcium influx or transport from intracytoplasmic calcium stores). EDTA abrogates the effect of A23187.[7] TPA, having a diacylglycerol-like structure, substitutes for diacylglycerol rather than by inducing the formation of diacylglycerol. TPA increases the affinity of protein kinase C

for calcium[8] but does not provoke a significant increase in Ca^{2+}.[9]

TPA and A23187 act synergistically in activating normal mouse and human B cells.[9-11] However, comparatively little is known of their effects on B-CLL cells. To explore the possibility of inducing differentiation in CLL cells, we studied the synergism between TPA and A23187 with respect to various aspects of B cell activation, including RNA synthesis measured by the uptake of ^{3}H-uridine and DNA synthesis measured by ^{3}H-thymidine uptake, which accompany morphological changes and differentiation to Ig-producing cells.

MATERIALS AND METHODS

Patients. Peripheral blood samples were obtained from 13 patients with B-CLL, two patients with prolymphocytic leukemia (B-PLL), and one patient with hairy cell leukemia (HCL). Diagnosis was based on typical clinical, morphological, cytochemical, and immunologic features. Clinical characteristics of the cases studied are outlined in Table 1. Mononuclear cells from the peripheral blood of four healthy donors were also investigated.

Phenotyping of cells. Mononuclear cells were isolated by Ficoll-Hypaque (Lymphoprep, Nyegaard, Oslo) density gradient centrifugation and analyzed by routine leukemia phenotyping.

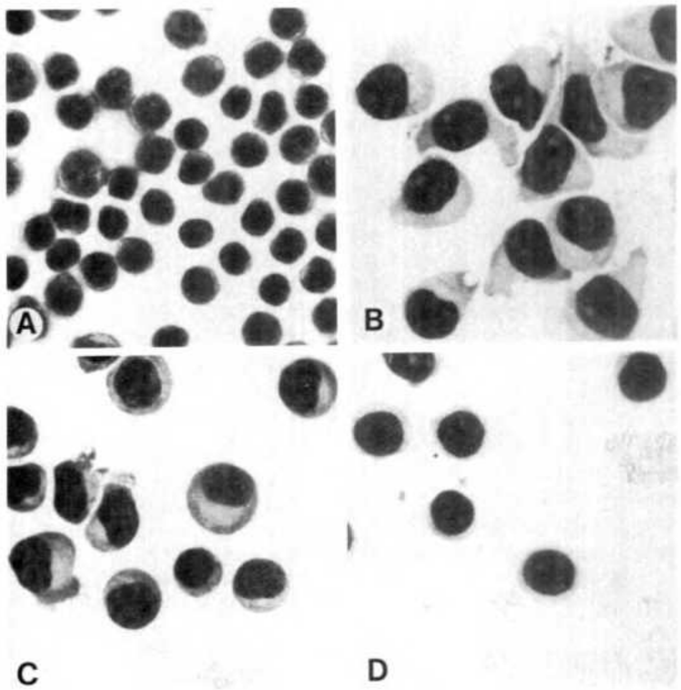

Fig 1. Morphology of B-CLL cells treated with TPA, A23187, or a combination of TPA plus A23187 (May-Grünwald-Giemsa stained; original magnification × 1,000; current magnification × 440). (A) Cells at day 0 (typical morphology of small, round B-CLL cells with scanty cytoplasm). (B) Cells after 72 hours of treatment with 2 × 10^{-8} mol/L TPA (enlarged, irregularly shaped cells with clear cytoplasm). (C) Cells after 72 hours of treatment with 2 × 10^{-8} mol/L TPA plus 0.5 μmol/L A23187 (enlarged, round to oval cells with basophilic cytoplasm, clear perinuclear zone, and eccentrically located nucleus). (D) Cells after 72 hours of treatment with 0.5 μmol/L A23187 (cells are enlarged but remained round with scanty, clear cytoplasm).

Direct and indirect immunofluorescence was performed by using the microtiter plate system as described in detail earlier.[12] Surface Ig expression was determined by direct immunofluorescence tests with fluorescein isothiocyanate (FITC)- or tetramethyl rhodamine isothiocyanate (TRITC)-conjugated goat antihuman Ig-specific antisera (Southern Biotechnology, Birmingham, AL). κ or λ chain expression was determined by double labeling with specific FITC- and TRITC-conjugated reagents. After incubation with specific monoclonal antibodies, cells were stained with FITC- or TRITC-conjugated goat antimouse Ig reagents. Monoclonal antibodies against the FMC7 and Tac antigens and reagents of the RF-series were kindly provided by Dr Jun Minowada (Fujisaki Cell Center, Okayama, Japan) and Professor George Janossy (Royal Free Hospital, London), respectively. The composite surface marker phenotypes of the patients studied are listed in Table 2.

Separation of cells. After Ficoll separation of mononuclear cells, plastic-adherent cells were depleted by incubation of the cell suspension on Nunc tissue culture plates (Roskilde, Denmark) for 90 minutes at 37°C. The resulting cell population was T cell depleted by rosetting for 45 minutes at 4°C with neuraminidase-treated sheep RBC (TCS, Berkshire, UK). Nonrosetting cells (B lymphocytes) were harvested from the interface of a second Ficoll gradient. The numbers of residual monocytes and T cells were determined by labeling of this population with MCS-2 (CD13), MY4 (CD14), or Leu-M3 (CD14) and Leu-4 (CD3) as described earlier.

Cell culture and in vitro stimulation. Cells were cultivated in RPMI 1640 medium (FLow Laboratories, Rickmansworth, UK) supplemented with 10% heat-inactivated fetal calf serum (Sera-Lab, Sussex, UK), penicillin/streptomycin (GIBCO, Uxbridge, UK), and L-glutamine (GIBCO) at a cell concentration of 2×10^6/mL in flat-bottomed 96-well microwell plates (Nunc) in a humidified 5% CO_2 atmosphere at 37°C. The cells were continuously incubated (without further addition or exchange of medium) for six days and harvested at 24-hour intervals. The following reagents were added: (*a*) none (control); (*b*) TPA (Sigma Chemical Co, Dorset, UK) at 2×10^{-8} mol/L; (*c*) TPA (2×10^{-8} mol/L) plus A23187 (Sigma) in various concentrations; and (*d*) A23187 at 0.5 µmol/L. In preliminary experiments it was found that concentrations of A23187 higher than 1.0 µmol/L were cytotoxic; the optimal range was 0.3 to 0.7 µmol/L A23187.

Morphological evaluation. Morphological changes were examined on cytocentrifuge slides (Shandon-Elliott, Sewickley, PA) prepared from all cell suspensions and stained with standard May-Grünwald-Giemsa solution. Adherence of cells to culture wells and formation of clusters were visually assessed in the microtiter plates under an inverted phase-contrast microscope.

Analysis of Ig production. The amount of IgM or IgG produced was measured by an enzyme-linked immunosorbent assay (ELISA). Microtiter plates (MicroElisa, Dynatech, Billinghurst, UK) were precoated overnight with rabbit antihuman IgM (Dako, Weybridge, UK) or goat antihuman IgG chain-specific antiserum (Sigma). After incubation of culture supernatants for two hours, alkaline phosphatase–conjugated goat antihuman antibodies specific for IgM or IgG (Sigma) were added for two hours. For visualization the substrate *p*-nitrophenyl phosphate (Sigma Phosphatase Substrate Tablets) was used. For determination of the monoclonality of the Ig produced, alkaline phosphatase–conjugated goat antihuman κ or λ light chain antibodies were used as the second step. All samples were tested for IgM and IgG production. The optical density of individual wells was determined with a Multiscan MC (Titertek, Flow Lab).

DNA and RNA incorporation assays. The cultures were pulsed with 1 µCi/well of ^{3}H-uridine or ^{3}H-thymidine (Amersham International, Amersham, UK) for one and six hours, respectively. The cells were harvested with a Multimash 2000 (Dynatech), and incorporation of ^{3}H-uridine into RNA and ^{3}H-thymidine into DNA was

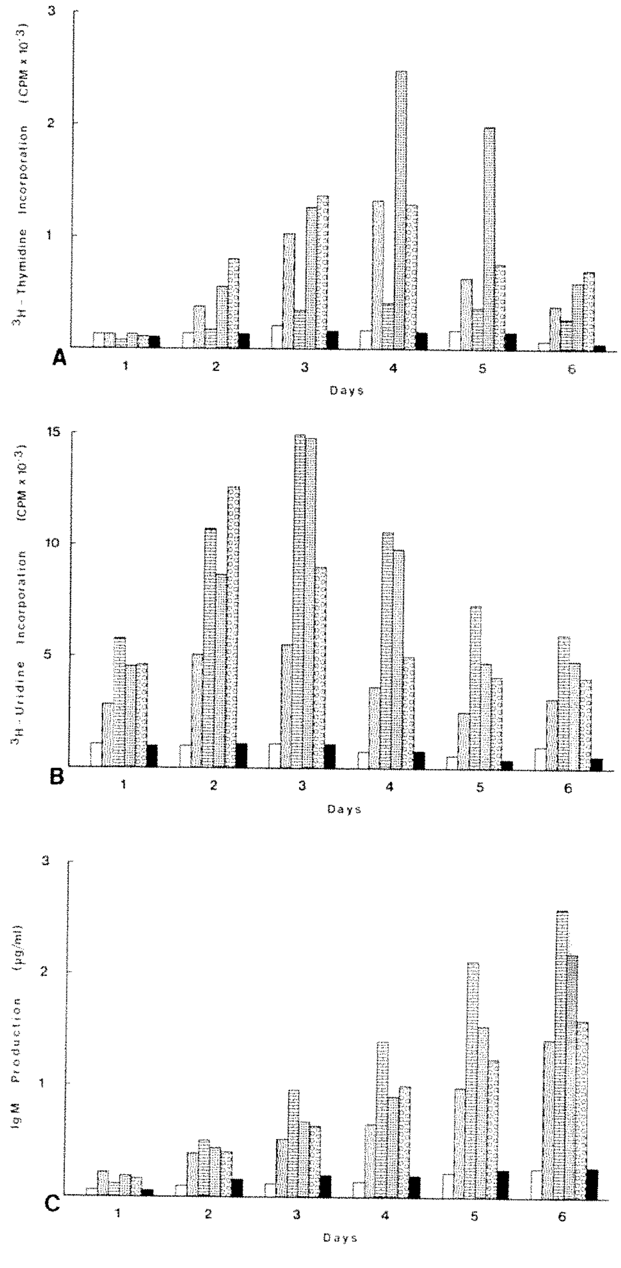

Fig 2. Response of B-CLL cells to continuous incubation with medium alone, TPA, A23187, and TPA plus A23187 in various concentrations measured at 24-hour intervals over six days. (A) ^{3}H-thymidine incorporation (patients 1 to 13). Uptake of ^{3}H-thymidine was significantly greater in the double-treated cultures than in the cultures treated with TPA or A23187 alone on days 3 and 4 (P = .025). (B) ^{3}H-uridine incorporation (patients 1 to 13). Uptake of ^{3}H-uridine was significantly greater in the double-treated cultures than in the cultures treated with TPA or A23187 alone on days 2 and 3 (P = .007). (C) IgM production (patient nos. 1 to 3 and 5 to 13). IgM production of the double-treated cells was significantly greater than in cultures treated with TPA or A23187 alone on days 4, 5, and 6 (P < .0001). □, Control; ▨, TPA; ▦, TPA + 0.7 µM A23187; ▤, TPA + 0.5 µM A23187; ▧, TPA + 0.3 µM A23187; ■, 0.5 µM A23187.

measured by standard liquid scintillation counting (LKB 1210 UltroBeta, Bromma, Sweden).

Statistical analysis. Comparisons between treatment groups were made by using paired *t* testing.

RESULTS

Cell populations. After depletion of T cells and adherent cells (monocytes, macrophages), the leukemia samples analyzed contained a neoplastic cell population of ≥98%. Less than 1% of the cells were positive for Leu-4 or RFT-2 (pan-T) or for monclonal antibodies detecting myelomonocytic antigens (MCS-2, MY4, Leu-M3).

The cells of all patients had morphological features typical of B-CLL, B-PLL, and HCL. The surface marker phenotypes are shown in Table 2. Besides characteristic morphology, the cases of B-PLL and HCL were positive for FMC7, which is a marker associated with but not specific for these leukemias.[13]

Normal B cells were obtained from the peripheral blood of healthy adults. However, these blood-borne normal B cells do not represent the normal counterparts to B-CLL cells (and therefore any comparison of the results is limited). B-CLL cells express the pan-T cell marker CD5, which is detected on <2% of normal peripheral blood B cells.[14] The T cell– and monocyte-depleted normal populations contained 28% to 42% cells stained by RFB7 (CD20).

Morphological changes. After 72 to 96 hours incubation, control B-CLL cells and A23187-treated cells were round, small, and nonadherent. TPA-exposed cells were either adherent to the surface of the culture dish with cytoplasmic elongations or clustered in densely packed, large clumps. Cells treated with TPA plus A23187 formed small clumps or aggregates that were nonadherent. B-PLL cultures showed similar growth changes.

HCL cells treated with either TPA alone or with the combination of TPA and calcium ionophore displayed prominent changes in their growth pattern as described elsewhere for TPA treatment of HCL[2]: the cells became strongly adherent and developed very long, thin, branched, cytoplasmic extensions. These cells could not be detached by vigorous shaking or pipetting with culture medium but required two cycles of incubation with trypsin solution.

On light microscopy, control B-CLL cells and A23187-exposed cells remained round with slightly increased cytoplasm. TPA-treated cells became larger, irregularly shaped, often with cytoplasmic vacuolization; however, the cytoplasm remained clear (Fig 1). In contrast, cells treated with the double stimulus enlarged but remained round to oval; the nuclei increased in size and moved to an eccentric position; the chromatin became finer, more evenly dispersed with nucleoli apparent; and the cytoplasm was deeply basophilic with a clear, "Hof"-like perinuclear zone. These plasmacytoid features were most pronounced in cells exposed to both TPA and 0.5 µmol/L A23187.

^{3}H-thymidine incorporation. In B-CLL cells, the double stimulus with TPA and A23187 increased the uptake of ^{3}H-thymidine into DNA significantly over the ^{3}H-thymidine incorporation found in cells treated with TPA alone ($P = .025$) (Fig 2A, Table 3). Maximal stimulation of proliferation occurred at 0.5 µmol/L A23187 plus TPA and peaked at day 4. At the highest ionophore concentration used, the response was less pronounced.

Both cases of B-PLL showed a severalfold higher incorporation of ^{3}H-thymidine (Table 3). In addition, the maximum response of B-PLL cells was at day 3 as opposed to day 4 in most B-CLL samples. The HCL cells were not responsive. In patient nos. 1 and 4 the response to the double stimulus did not surpass that to TPA alone; the cells from patient no. 3 could not be triggered to incorporate ^{3}H-thymidine (Table 4).

^{3}H-uridine incorporation. In the experiments summarized in Fig 2B, B-CLL cells were stimulated with either TPA or A23187 alone or TPA in combination with varying doses of A23187. The combined agents led to ^{3}H-uridine incorporation into RNA that was significantly increased over the activation with one of the inducers alone ($P = .007$). The highest peak was seen at day 3 with 0.7 µmol/L A23187 plus TPA.

Although the response of cells from patient no. 15 (B-PLL) was of about the same magnitude as seen in the B-CLL cultures, ^{3}H-uridine incorporation of cultures from patient no. 14 (B-PLL) was about four- to sixfold higher (Table 5). In both cases of B-PLL, the maximum response in terms of ^{3}H-uridine uptake occurred on day 2, whereas it was uniformly on day 3 in B-CLL cells. HCL cells did not incorporate significant amounts of ^{3}H-uridine (Table 5).

Ig production. The effect of the combined action of TPA and A23187 on Ig production was assessed in an ELISA

assay. TPA induced a clear increase in Ig production in B-CLL cells (Fig 2C). This increase was not found in control or in A23187-treated cultures. The combination of the two agents induced the production of significantly higher amounts ($P < .0001$) of Ig than the exposure to TPA alone. The double stimulation with TPA plus 0.7 μmol/L A23187 was the most effective.

For all cases, IgM, IgG, and light chain production was measured. The response to TPA with or without calcium ionophore was monotypic in light and heavy chains and corresponded to the Ig light and heavy chains found by surface staining. In none of the cultures with IgM-positive cells was IgG or an increase thereof detected at levels above the sensitivity of the assay.

The B-PLL cultures showed a similar pattern of response in Ig production (Table 6). The HCL cells could not be induced to increase their Ig production (Table 6). In cultures from patient no. 4 (IgG isotype), TPA caused the cells to produce IgG; however, the response to the double stimulus was not higher than that to TPA alone (Table 4).

DISCUSSION

Recent studies observed a strong synergistic action of phorbol ester and calcium ionophores on the cell proliferation of normal human and murine B cells.[10,11,15,16] It was found that proliferation, cell size, and expression of the activation markers Tac, transferrin receptor, and HLA-DR of normal B cells induced by TPA was greatly enhanced by A23187.[10]

In a preliminary congress report on a small series of patients, Clevers et al have described that A23187 and phorbol esters act synergistically in the activation of B-CLL cells.[17] However, due to the lack of methodological, clinical, and immunophenotype data and the absence of a detailed presentation of the results, their report and the work presented here cannot be compared directly.

The present study demonstrates clearly that double stimulation of B-CLL cells with TPA and A23187 has significantly stronger effects than either reagent alone. The phenotypic changes in B-CLL cells induced by TPA have been described previously.[18-22] However, although the calcium ionophores used alone trigger cell activation in normal B and T cells,[4,5,23] we and others[7] found that A23187 alone is not effective in B-CLL cells. This discordance may be a consequence of the differentiation blockage of the malignant cells or may occur because T-depleted cell populations from normal donors have a higher percentage of contaminating T cells that are highly responsive to calcium ionophores. In preliminary experiments comparing B-CLL samples before and after T cell depletion we found that as few as 5% to 10% contaminating T cells altered these results significantly. It is therefore essential to purify the malignant B cell population and to verify the number of T cells in the resulting samples.

Higher concentrations of A23187 have been reported to inhibit DNA synthesis.[24,25] The range of useful doses of A23187 was very narrow in normal[25] and B-CLL cells.[7] In our system, the doses that synergized optimally with the phorbol ester to promote differentiation were in the narrow range of 0.3 to 0.7 μmol/L.

Interestingly, cell cycle progression studies on normal quiescent tonsillar B cells indicated that the combination of TPA and calcium ionophore stimulated essentially all cells,

whereas TPA alone triggered only a proportion of cells.[26] We confirm these findings by observing that the majority of the cells per sample changed their morphology to plasmacytoid variants upon exposure to the double stimulus. Similarly, the observed increase in thymidine and uridine uptake probably represents stimulation of a higher proportion of cells by TPA and calcium ionophore together than either in isolation. However, it remains possible that nucleotide uptake is enhanced due to increased stimulation of a minority subpopulation of cells.

Using normal tonsillar, spleen, and peripheral blood B cells, Clevers et al[10] demonstrated that TPA and A23187 did not induce differentiation of these cells to Ig production. These results stand in contrast to our experiments where the synergy of the two stimuli clearly caused a strong increase of Ig production in B-CLL cells. However, these authors noted that doubly stimulated normal B cells subsequently exposed to B cell differentiation factor (BCDF) produced large amounts of Ig. This suggests that TPA plus calcium ionophore provided increased responsiveness of normal B cells to differentiation factors.[10] It is not clear why the malignant cells treated with the double stimulus responded promptly by secreting significant amounts of Ig with no further requirement for BCDF. One possible explanation is the autocrine secretion of differentiation-inducing factor(s),[27] and this possibility is being explored by using several growth/differentiation factors.

The morphology of PLL cells and CLL cells in prolymphocytoid transformation resembles that described for activated normal B cells,[28] and these B-PLL cells respond more strongly than B-CLL cells to the double stimulus. On the other hand, HCL cells did not respond to phorbol ester and calcium ionophore in terms of differentiation toward plasma cells. Despite the fact that HCL cells have been shown to be of B cell derivation[29] and have even been classified by immunologic means as "preplasma cells,"[30] they did not develop plasmacytoid features typical of secreting B cells either during treatment with TPA alone[2] or during exposure to the double stimulus. However, certain morphological changes were found in treated HCL cells, and the discrepancy between morphological alterations of HCL cells and their unresponsiveness in other respects is of interest. The lack of responsiveness of HCL cells might be the result of a possible dependence on growth/differentiation factor(s). Further studies are required to address this question.

In summary, the results presented indicate that (a) phorbol ester and calcium ionophore act synergistically in B-CLL in inducing proliferation and differentiation and (b) the capacity of B-CLL cells to differentiate in response to signals of the second messenger pathway is intact.

Limiting-Dilution Analysis for the Determination of Leukemic Cell Frequencies After Bone Marrow Decontamination With Mafosfamide or Merocyanine 540

By A. Porcellini, N. Talevi, M.T. Marchetti-Rossi, M. Palazzi, A. Manna, G. Sparaventi, C. Delfini, and M. Valentini

To simulate a leukemia remission marrow, cell suspensions of normal human bone marrow were mixed with human acute lymphoblastic or myelogenous leukemic cells of the CCRF-SF, Nalm-6, and K-562 lines. The cell mixtures were incubated in vitro with mafosfamide (AZ) or with the photoreactive dye merocyanine 540 (MC-540). A quantity of 10^4 cells of the treated suspensions was dispensed into microculture plates, and graded cell numbers of the line used to contaminate the normal marrow were added. Limiting-dilution analysis was used to estimate the frequency of leukemia cells persisting after treatment with the decontaminating agents. Treatment with AZ or MC-540 produced a total elimination (ie, 6 logs or 5.3 logs respectively) of B cell acute leukemia cells (CCRF-SB), whereas nearly 1.7 logs and 2 logs of K-562 acute myelogenous blasts were still present in the cell mixtures after treatment with MC-540 and AZ, respectively. Treatment of the Nalm-6–contaminated cell mixtures with AZ resulted in 100% elimination of clonogenic cells, whereas nearly 80% decontamination was obtained with MC-540. Our results suggest that treatment with AZ could be an effective method of eliminating clonogenic tumor cells from human bone marrow. MC-540, shown by previous studies to spare sufficient pluripotential stem cells to ensure hemopoietic reconstitution in the murine model and in clinical application, has comparable effects and merits trials for possible clinical use in autologous bone marrow transplantation.

AUTOLOGOUS BONE MARROW transplantation (ABMT) is now being used as an alternative transplant approach for patients in remission of acute leukemia who lack an HLA-identical donor. The major stumbling block in ABMT still remains the high relapse rate as compared with allogeneic marrow transplantation,[1] evidently due to occult leukemic cells that contaminate the remission marrow. Several methods for eliminating these cells from autologous marrow have been proposed, but the efficacy of the purging procedures has yet to be established. Although the advantage of marrow purging is uncertain in acute nonlymphocytic leukemia (ANLL) treated by autotransplantation in the first complete remission (CR), there are some indications that cleansing of the marrow is linked with improved survival in autograft recipients in the second CR.[1] Despite the preliminary nature of these data and the need for more prolonged follow-up, in vitro treatment of the autologous marrow harvest to eliminate or at least reduce leukemic cells would seem a desirable goal.[2]

4-hydroperoxycyclophosphamide (4HC) and 4-hydroxazaphosphorine or mafosfamide (AZ), both congeners of cyclophosphamide (CY), are the most commonly used drugs for chemical purging in ABMT. Evidence from animal models that 4HC and AZ may purge marrow of clonogenic cells[3,4] while sparing the pluripotential stem cells[5] has been presented previously. Furthermore, 4HC- or AZ-treated human marrow cell suspensions are able to reconstitute the hematopoietic system after ablative therapy despite a marked reduction in detectable progenitor cells.[2,6-10]

The photoreactive dye merocyanine-540 (MC-540) binds to fluid like domains in the outer leaflet of the lipid bilayer of intact cell membranes.[11-14] Electrically excitable cells and some immature hematopoietic precursor cells show exceptional permeability to MC-540.[15]

Photoexcitation of membrane-bound dye with light of suitable wavelength causes increased dye uptake, impairment of the normal permeability properties of the plasma membrane, and eventually, cell death.[15,16] Sieber et al[17-20] have studied the sensitivity to MC-540–mediated photolysis of hematopoietic precursors and pluripotential stem cells as compared with the lymphocytic leukemia cell line L1210. Their findings of a much greater reduction in the L1210 cell number suggest that this dye might serve as a cleansing agent for ABMT.

Although marrow cleansing offers an interesting approach because the aforementioned research and clinical trials have shown that this procedure is not harmful to pluripotential stem cells and not hazardous, the real efficacy of this procedure in terms of residual clonogenic cell removal still needs to be determined. Several assays have been developed in an attempt to solve this problem.[21-26]

This study was designed to test the ability of AZ or MC-540 to eliminate clonogenic leukemic cells from a mixture of leukemic and normal human bone marrow mononuclear cells (HBMMC). For this purpose, a highly sensitive in vitro clonogenic assay was developed by using established human leukemia cell lines. This assay, which enabled enumeration of residual leukemia cells, was sufficiently sensitive to detect as much as a 6-log reduction in leukemia cells that contaminate human bone marrow.

MATERIALS AND METHODS

Preparation of bone marrow suspensions. Bone marrow specimens were aspirated into heparinized syringes from the posterior iliac crests of healthy volunteers after obtaining their informed consent. The mononuclear marrow cell line suspensions were prepared as described previously.[27]

Leukemia cell lines. The following established cell lines were used: pre-B cell line Nalm-6; B cell line CCRF-SB, and the myeloid-monocytic line K-562. All cell lines were kindly supplied to us by Dr Hansen, Fred Hutchinson Cancer Research Center, Seattle. The cell lines were maintained in RPMI 1640 medium with 15% fetal calf serum (FCS), 1% penicillin-streptomycin antibiotics (10,000 U), 1% L-glutamine, and 1% minimal essential medium (MEM) sodium pyruvate solution and were kept at 37°C in a fully humidified incubator with 5% CO_2. The cells were maintained in exponential growth by keeping the cell concentration in a range from 0.5 to 1.0×10^6 cells/mL. The viability of all cell lines was $\geq 90\%$ as judged by trypan blue dye exclusion.

Purging agents. AZ (Asta Werke, Bielefeld, FRG) was diluted with TC 199 to a concentration of 10 μg/mL immediately before use.

MC-540 (Eastman Kodak Co, Rochester, NY) was diluted from a freshly prepared stock solution of 1 mg/mL in 50% (vol/vol) water-ethanol to a final concentration of 15 μg/mL.

Purification with AZ. To simulate remission bone marrows from leukemia patients, 10^6 leukemia cells of the CCRF-SB, Nalm-6, or K-562 cell lines were mixed with a 19-fold excess of HBMMC; the suspensions were adjusted to 20×10^6 cells/mL with TC 199 medium, placed in 12-mL plastic tubes, and incubated for 30 minutes at 37°C in a water bath with 50 or 100 μg/mL of AZ. After incubation, the cell suspensions were placed in ice for five minutes to stop the reaction and then washed twice in RPMI 1640.

Photosensitization with MC-540. A quantity of 2×10^5 leukemia cells of the CCRF-SB or K-562 lines were mixed with a 19-fold excess of HBMMC; the suspension was adjusted to 4×10^6 cells/mL with MEM α medium (GIBCO, Grand Island, NY), containing 15% FCS (Seromed, FRG) and placed in Petri dishes, and 15 μg of MC-540 dissolved in 50% ethanol was added. Clear polystyrene tissue culture dishes (60×15 mm) containing the cell suspension were placed in the center of a rectangular frame (58×40 cm) fitted with six daylight fluorescent tubes (Phillips, TL M 20W/133 RS, 56 cm long), three above the dishes and three below, and illuminated for 45 or 90 minutes. Illumination at each side of the sample (at 20 cm from the light source) was 0.0007 W/cm^2.

The dishes were shaken manually every five minutes to keep the cells in suspension. After light exposure, the cell suspensions were washed twice in MEM α medium containing 5% FCS.

Limiting-dilution Assay. After incubation with AZ or MC-540, 10^4 cells from those treated were suspended in 100 μL RPMI 1640 and plated in microculture plates (Nunc, Roskilde, Denmark).

Graded cell numbers of the same line used to contaminate the HBMMC were suspended in 100 μL RPMI 1640 containing 15% pooled human serum and added to the treated cell feeders and incubated for 13 days. Refeeding of the cultures with fresh medium was carried out every third day.

Twelve hours before harvesting, the cells were pulse-labeled with 1 μC; ^{3}H-thymidine. The cells were then harvested by means of a Skatron apparatus (Lierbyen, Norway), and incorporated thymidine was quantitated by scintillation counting.

Statistical analysis. Clonogenic cell frequency was determined by the maximum likelihood (ML) method from the plot of the Poisson distribution relationship between the cell number seeded per well and the percentage of negative wells.

The ML equation was obtained by modifying the Taswell method[28]; ML regression analysis, x-intercept values, and confidence limits on the population regression line for prediction of y at a given value of x were obtained by using the MINUIT computer program (CERN Library, Geneva) in a VAX-750 computer.

RESULTS

For this study, a limiting-dilution (LD) analysis was adopted to evaluate the frequency of leukemic cells of the CCRF-SB, Nalm-6, and K-562 lines surviving in an HBMMC mixture after treatment with AZ or MC-540.

The mean ^{3}H-thymidine uptake in the wells in which no leukemia cells were added (ie, containing only 10^4 cleansed HBMM cells) was determined (Fig 1). Only wells that exceeded the mean of the control wells by at least 3 SD were scored as positive (responders). The number of responders increased progressively with the number of blasts added (Fig

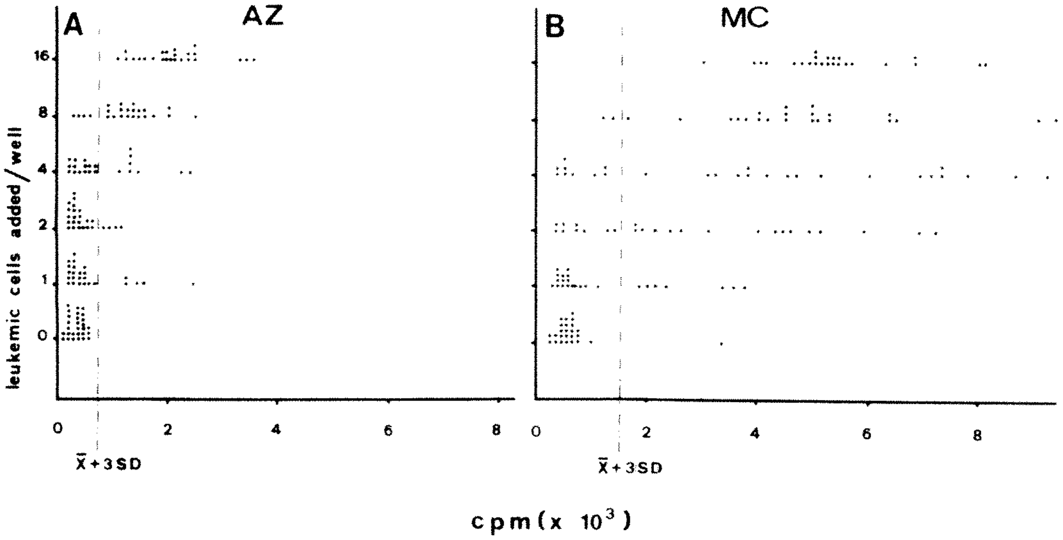

Fig 1. Distribution of ^{3}H-thymidine uptake in an LD assay for residual CCRF-SB lymphoblasts. Groups of 24 microwells containing suspensions of 10^4 mixed cells treated with AZ (lefthand panel) or MC-540 (right-hand panel) were seeded with graded numbers of CCRF-SB cells per well (see Materials and Methods) and incubated for 13 days. The cell proliferation rate was assayed by ^{3}H-thymidine uptake. The dotted line represents 3 SD above the mean ^{3}H-thymidine uptake of the nonresponding microcultures with no added CCRF-SB clonogenic cells.

1). Figures 2 and 3 represent the data obtained from LD assays of cleansed HBMM and leukemic cell mixtures in which the equations of the line of best fit were derived by ML methods.

The cloning efficiencies of CCRF-SB, K-562, and Nalm-6 cells in this experiment, calculated as the slope of the regression line when the ordinate is the natural log of the percent nonresponders (Fig 2), were 22%, 44%, and 26% respectively.

The estimate of the number of leukemic cells still present in the cell mixtures after cleansing is represented by the x-intercept of the regression line. In the experiment shown in Fig 2, complete decontamination of CCRF-SB and Nalm-6 cells (panels A and C) in each well containing 10^4 mafosfamide-purged mixture cells was obtained, and 0.08 K-562 leukemic cells (Panel B) survived after treatment.

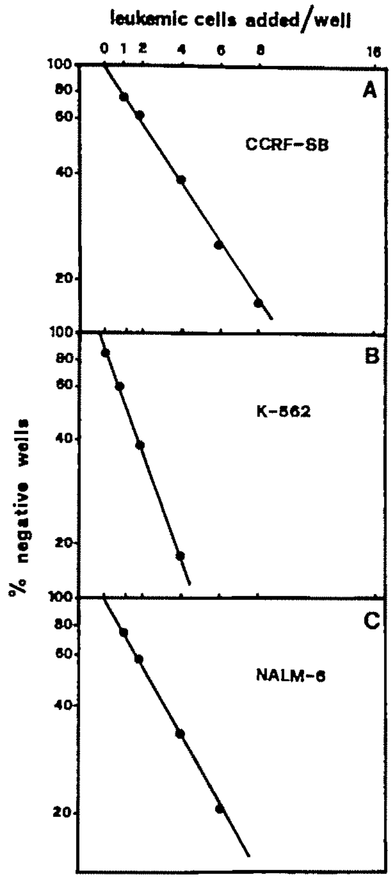

Fig 2. LD analysis of mafosfamide-treated bone marrow mononuclear cells previously contaminated with 5% of one of the following clonogenic cell lines: CCRF-SB lymphoblasts (A), myelogenous K-562 cells (B), and pre-B Nalm-6 cells (C). The percentage of nonresponding wells is plotted against the number of clonogenic cells added to each well containing 10^4 purged mixture cells. The wells were scored as positive (responders) or negative (nonresponders) according to whether the ^{3}H-thymidine uptake was greater or less than the threshold 3 SD above the mean of the nonresponding microcultures with no added clonogenic cells. The lines of best fit, as determined by ML regression analysis, x-intercept values, and confidence limits on the population regression line, were originated by the MINUIT computer program in a VAX-750 computer.

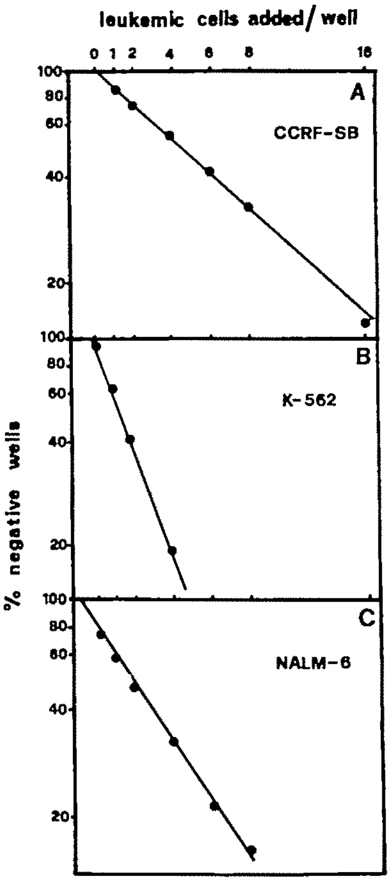

Fig 3. Results obtained from LD analysis of MC-540-treated bone marrow mononuclear cells; details are as in Fig 2.

The 95% confidence intervals (95% CI) for the value of the x-intercept of this experiment, calculated as described by Cox and Hinkley,[29] were −0.71 to 0, −0.28 to 0, and −0.39 to 0 for the three leukemic lines respectively. Thus, there was <5% probability that the frequency of leukemic cells would be greater than $1/10^4$ cleansed mixture cells. It should be noted that the threshold sensitivity of this assay was about one clonogenic cell per 10^4 HBMM cells (Figs 2 and 3).

Similar results were obtained in two replicate experiments in which a complete clearing of all leukemic cells was obtained, with the exception of 0.16 residual K-562 blasts in one single experiment. In all these replicate studies, the 95% CI indicated that there was always a 5% probability that the frequency of residual blasts would be $>1/10^4$ purged mixture cells.

Figure 3 shows the results obtained by purging the cell mixtures with MC-540. With this cleansing agent, the calculated residual clonogenic cells in each well were 0 CCRF-SB cells (95% CI, <0.38, panel A) and 0.11 K-562 cells (95% CI <0.53; panel B). Pre-B Nalm-6 cells proved less responsive to MC-540 in that 1.78 residual leukemic cells (95% CI, <4.74) were found after photosensitization. The cloning efficiencies of leukemic cells in this experiment as judged by the ML regression line were 13.4% (CCRF-SB), 40.3% (K-562), and 8.7% (Nalm-6).

These results were confirmed in two replicate experiments. The B cell lymphoblasts were eliminated completely by the MC-540 treatment; however, 0.023 to 0.18 clonogenic cells were present after purging cell mixtures contaminated with the K-562 cells. Again, the 95% CI confirmed that there was a 5% probability of the residual blasts being present at a frequency greater than $1/10^4$ purged mixture cells.

The effectiveness of both AZ and MC-540 proved to depend directly on the dose level (AZ) and the light exposure time (MC-540) (Fig 4). Incubation of the cell mixture containing CCRF-SB clonogenic cells with 50 μg/mL of AZ caused decontamination of 3.2 logs; hence about 620 clonogenic cells persisted after purging. The cloning efficiency in this experiment was 8.6%. By increasing the dose of AZ to the usual level of 100 μg/mL, complete clearing of CCRF-SB lymphoblasts was obtained, and the cloning efficiency was increased to 16.5% (Fig 4, left-hand panel).

With an exposure time of only 45 minutes, MC-540 was able to decrease the CCRF-SB lymphoblast frequency in the cell mixture by 3.7 logs. About 40 clonogenic cells were present after purging, and the ML regression line showed a cloning efficiency of 2.3%. By contrast, an exposure time of 90 minutes not only caused complete clearing of the lymphoblasts but also increased the cloning efficiency to 7.3%. By lengthening the exposure time to 120 minutes, we could not detect a higher degree of decontamination; however, the cloning efficiency obtained in this case was 26.1% (Fig 4, right-hand panel).

DISCUSSION

Removal of occult malignant cells may be of critical importance for improving the efficacy of ABMT in acute leukemia.[1,7] A major complication in this procedure is the impossibility of evaluating the effects of in vitro treatment both on cells responsible for engraftment and on clonogenic cell removal.

Evidence obtained in experimental models that 4-HC, AZ, or MC-540 does not impair the ability of marrow cell suspensions to restore hematopoiesis has already been presented.[3,5,18]

A test for pluripotential stem cell survival in humans is not currently available. However, a body of evidence from both experimental and clinical studies indicates that a sufficient number of cells responsible for hematopoietic reconstitution survive exposure to either CY derivatives or MC-540. Indirect confirmation thereof was obtained in two in vitro studies. Normal human marrow cell suspensions treated with 4-HC and then seeded in a long-term marrow culture system, although completely devoid of detectable progenitor cells, showed recovery of CFU-GM.[30] A similar study in which marrow from leukemic patients in CR was incubated with AZ obtained comparable results.[8] Both studies tested a variety of drug dose levels including those commonly used in clinical ABMT and clearly indicated that purged marrow suspensions retain their self-regenerating ability.

The effect of both 4-HC and AZ on normal hematopoiesis was evaluated by Gordon et al[31] and Deglantoni et al[32] by means of a new colony assay[33] designed to detect very immature blast progenitor cells. Both these studies showed that in vitro treatment with either drug did not impair the formation of blast colonies containing very primitive cells capable of self-renewal and differentiation.

An indirect but persuasive demonstration that ex vivo purging with CY derivatives is not harmful to pluripotential stem cells may be inferred from the prompt restoration of hematopoiesis after reinfusion of purged marrow suspensions following myeloablative treatment.[2,7-10] In these reports the

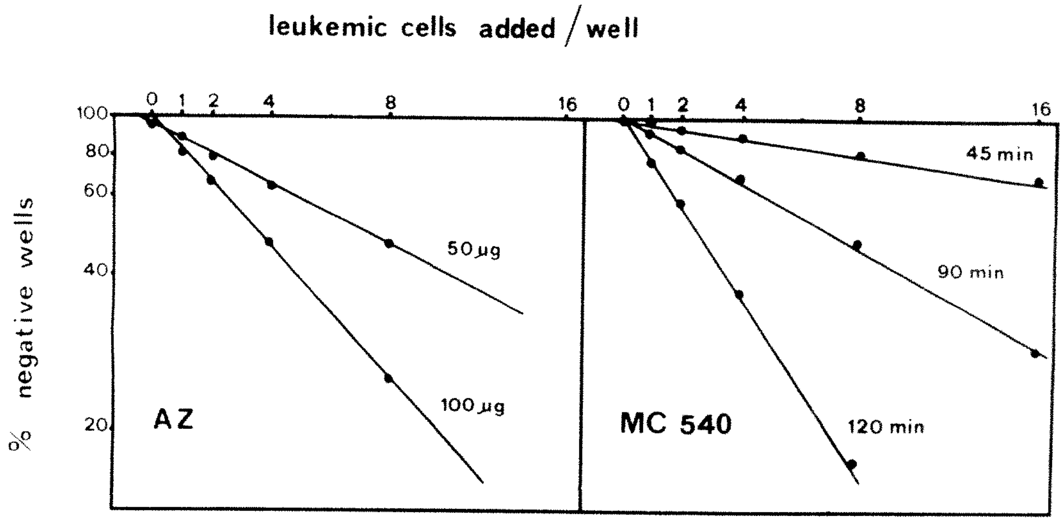

Fig 4. Semilog plots of the proportion of nonresponding microcultures for each dose of clonogenic cells added to wells containing suspensions of 10^4 cleansed cells which were previously contaminated with 5% CCRF-SB lymphoblasts. Results were obtained from LD analysis of cell mixtures decontaminated with AZ or MC-540. Lefthand panel, 19 × 10^6 HBMM cells contaminated with 10^6 CCRF-SB lymphoblasts were treated with 50 or 100 μg/mL of AZ. Righthand panel, 3.8 × 10^6 HBMM cells contaminated with 2 × 10^5 CCRF-SB lymphoblasts were incubated with 15 μg/mL MC-540 under fluorescent lights for 45, 90, and 120 minutes.

median time of hematopoietic recovery was comparable to that obtained in ABMT with untreated marrow.

In the first clinical application of ABMT purged with MC-540, the photoreactive dye showed that it did not compromise the graft's ability to reconstitute the hematopoietic system.[34]

The other major concern in ex vivo marrow cleansing is to quantitate the number of clonogenic cells present in the remission marrow and to estimate those removed by the cleansing procedures.

Unfortunately there is no means available for detecting minimal residual disease in remission marrow. However, by using leukemia cell lines it is possible to develop clonogenic assays that measure the elimination of malignant cells from an excess of normal HBMMC. Although these model systems may differ somewhat from the clinical situation, such in vitro simulation experiments permit evaluation of the efficiency of the drug used in terms of leukemic cell removal.

The LD assay has been used extensively to study the response of antigen-reactive cells both in animal models[35,36] and in humans.[37-39] To meet our requirements, we have adapted an LD assay originally described by Moretta et al[40] and modified by Martin and Hansen.[41]

In all the experiments performed, the ML regression lines were consistent with the single-hit model (Figs 2 and 3). Assuming that the test mixture cell suspensions are homogeneous, the leukemic cells sampled into each microwell will occur randomly according to the Poisson probability distribution. In a single-hit model, it is not possible to determine whether a positive response is due to one or more cells. However, no response occurs in the absence of cells.

Therefore, the zero term of the Poisson equation will indicate that the proportion of nonresponders is a negative logarithmic function of the number of leukemic cells added to each well; hence in our study, it was possible to establish an equation for the line of best fit to calculate the leukemic cell frequency in each sample. The efficacy of this assay hinges on its ability to provide quantal discrimination between wells with cell growth (responders) and wells with no cell growth (nonresponders).[41] Definition of the latter is somewhat arbitrary because when total decontamination (100% purging) was not attained some leukemic cells were present in the wells after treatment even when none were added for the LD assay. However, in all our experiments, the outliers in ^{3}H-thymidine uptake were quite obvious (Fig 1B) and were disregarded when calculating the cutoff between negative and positive wells. In some cases, when there is a high number of residual leukemic cells or when microcultures are seeded with an excessive amount of leukemic cells, the increased proliferation rate of the leukemic cells, as measured by ^{3}H-thymidine incorporation, can give rise to false-negative results and hence an unexpectedly high proportion of negative wells. In our microtray assay system, although cultures are refed periodically, medium supply may become a limiting factor in the case of an excessive cell proliferation rate. It is possible to adjust the LD assay for different degrees of blast cell purging by changing the number of clonogenic cells seeded per well.

LD assay techniques usually involve the use of irradiated feeders to which increasing numbers of cells containing an unknown proportion of precursors are added. Hence, it follows that when no precursors are added to the irradiated feeder-containing wells 100% nonresponders will be obtained, and the regression line will necessarily include the origin. In our experiments, the feeders (ie, 10^4 purged HBMM cells) contained an unknown proportion of residual leukemia cells to which further successive known doses of blasts were added. Thus, one would not expect semilog plots of blast cells added and the proportion of nonresponders to necessarily include the origin, except in the case in which no residual blasts remained in the wells.

Should residual blasts persist after purging, the x-intercept that represents an estimate of the number of blast cells that would have to be removed from the feeders to obtain 100% nonresponders can be calculated from the ML regression line.

In our model system, after AZ or MC-540 treatment at the highest dose level tested, no acute leukemia CCRF-SB lymphoblasts were detectable in the cell mixtures. In the Nalm-6–contaminated mixtures, AZ obtained 100% decontamination, whereas the figure for MC-540 was 80%. In the mixtures containing K-562 cells, both agents yielded a result of 99.97% decontamination. Our data do not indicate whether it would be possible to obtain a higher degree of decontamination, either by increasing the dose level of AZ or by increasing both the dose level and the light exposure time of MC-540. Clinical experience has shown that 100 μg/mL of AZ is the maximum safe dose level for this drug, and further increases might be critical.[2] As far as MC-540 is concerned, further studies are needed to determine potential harmful effects on pluripotential stem cells at doses higher than those used in our model.

It is possible that occult leukemic cells contaminating a remission marrow are more difficult to eliminate than exponentially growing leukemic cells such as those used in our model system. It may be more difficult to obtain 99.97% decontamination in the clinical situation if the clonogenic leukemic cells are quiescent or slowly cycling. Thus the figure of 99.97% may represent an overestimate of the cleansing efficiency of both AZ and MC-540. Moreover, because the threshold limit for detection with this assay is about one per 500 clonogenic cells, it is evident that when complete decontamination (as calculated by our LD assay) is obtained as many as 3 to 4 logs of clonogenic cells could persist after purging, given the supposed initial leukemic cell population in the autologous harvest of between 10^6 and 2×10^7 cells.

It has been suggested that the susceptibility of tumor cells to alkylating agents may be due to a decrease in their aldehyde dehydrogenase content (compared with normal cells) rather than to their proliferative state.[42-44] However, actively proliferating cells are likely to prove more susceptible to alkylators than are dormant cells. Moreover, if ABMT is performed in the second or higher CR, residual malignant cells may have developed a relative resistance to alkylating agents. One potential advantage of using MC-540 is that this agent causes impairment of the normal permeability properties of the plasma membrane regardless of the proliferation rate of target cells. This suggests that this approach could effectively eliminate noncycling malignant cells as well.[16]

The viability of marrow treated with MC-540 is yet to be evaluated in a phase I clinical trial. However, our in vitro data suggest that chemical treatment of marrow with this photoreactive dye might provide a new approach for removing malignant cells, regardless of their cycling rate, without unduly damaging the pluripotential stem cells.

ACKNOWLEDGMENT

Evidence for Peripheral Blood B Lymphocyte but Not T Lymphocyte Involvement in Multiple Myeloma

By James Berenson, Rex Wong, Kenneth Kim, Nathaniel Brown, and Alan Lichtenstein

Because there is controversy regarding whether subsets of peripheral blood lymphocytes (PBLs) are part of the malignant clone in patients with multiple myeloma, we studied this question by immunoglobulin and T cell receptor gene analysis. Southern blot analysis with antibody probes demonstrated clonal immunoglobulin gene rearrangements in PBLs of seven of nine patients that were identical to those seen in their marrow plasma cells. Circulating plasma cells were not detected in any of these patients. In contrast, no patient demonstrated clonally rearranged T cell receptor genes. In one sequentially studied patient, PBLs obtained at diagnosis when he had stage I (Durie-Salmon) contained only germline DNA, while analysis of PBLs at relapse (stage III) revealed a clonally rearranged band. These data confirm the notion that circulating lymphocytes in patients with myeloma are part of the malignant clone and, furthermore, these malignant cells are of B cell rather than T cell lineage.

©1987 by Grune & Stratton, Inc.

MULTIPLE MYELOMA is regarded as a disease of immunoglobulin-producing cells. Although the predominant cell of this marrow-based neoplasm has the morphological characteristics of a plasma cell,[1] data have accumulated that other lymphoid cell types are also part of the malignant process.[2-5] In patients, a significant number of peripheral blood lymphocytes (PBLs) bear the unique paraprotein idiotype found in the plasma cells. These data would suggest that an earlier cell in B cell differentiation is part of the malignant clone. Moreover, some workers have shown that idiotype-bearing T cells also circulate in the peripheral blood of these patients.[6]

On the other hand, King and Wells[7] have demonstrated that the cytophilic IgG idiotype may remain bound to Fc receptors on PBLs even after extensive washing and incubation. These investigators failed to show any evidence of PBLs with an endogenous surface idiotype when using a rosette assay. Recently, two other groups have also not found significant numbers of idiotype-bearing PBLs when using similar assays.[8,9] Thus, there is controversy regarding whether PBLs are part of the malignant clone in multiple myeloma and, furthermore, which lymphocyte subsets are involved in the disease.

To address this controversy, we have searched for antibody and T cell receptor (TCR) gene rearrangements to determine whether significant numbers of clonal malignant B and/or T lymphocytes exist in the peripheral blood of patients. Gene rearrangements can be used to accomplish this goal because clonally derived B or T cell populations have unique rearrangements of antibody or TCR genes, respectively. This DNA analysis avoids the problems with passively adsorbed antibody which has confounded previous studies.

MATERIALS AND METHODS

Patients. Nine patients with multiple myeloma as defined by the Myeloma Task Force were studied.[10] All patients underwent bone marrow examination, serum protein electrophoresis, immunoelectrophoresis, bone surveys, routine chemistries, CBCs, and 24-hour urine collection for determination of creatinine and protein. Patients were staged according to the Durie-Salmon classification.[11]

Isolation of peripheral blood lymphocytes, granulocytes and bone marrow plasma cells. Peripheral venous blood and bone marrow samples were obtained from all nine patients after informed consent and in accordance with the Human Subjects Review Boards of the Veteren's Administration Wadsworth and UCLA Medical Center. Peripheral blood was centrifuged to separate the cells from the serum. The cells were exposed to Histopaque (Pharmacia Fine Chemicals, Piscataway, NJ) 1077 and 1119 density gradient separation. This technique yields >98% pure granulocytes at the 1077/1119 interface, and these cells do not show antibody gene rearrangements in Southern blot analysis.[12] The mononuclear cells appear at the 1077/Hanks' balanced saline solution interface, and the monocytes are removed from this fraction by adherence to plastic dishes, which leaves highly purified PBLs (>98%). Bone marrow was exposed to Ficoll-Hypaque (Pharmacia) density gradient separation to yield enriched populations of plasma cells.

Southern blot analysis. Genomic DNA was prepared from PBLs, granulocytes, and bone marrow plasma cells on each patient according to the method of Perry et al.[13] The DNA was digested with restriction endonucleases *Bam*HI, *Eco*RI or *Hin*dIII (Bethesda Research Laboratories, MD). Ten micrograms of digested DNA was electrophoresed in 0.6% agarose gels at 1 to 2 V/cm for 42 hours and transferred to nylon membranes by the method of Southern.[14] Parallel lanes of similarly digested granulocyte, PBL, and plasma cell DNA samples from each patient were electrophoresed on the same agarose gel.

Recombinant probes for the human heavy chain immunoglobulin (Ig) gene segments J_H and $C_{\gamma 4}$ were donated by L. Hood et al (California Institute of Technology, Pasadena, CA) and were subcloned in pBR322. The J_H probe is a 3.2-kilobase pair (kb), human genomic fragment extending from JH2 to the *Hin*dIII site in the J_H-C_μ intervening sequence.[15] The $C_{\gamma 4}$ probe is a 2-kb genomic clone containing the complete sequence of $C_{\gamma 4}$; this probe hybridizes with all four C_γ-subclass gene fragments, which are reported to be ≥90%

homologous.[16] The C_α probe is a 4.2-kb *Bam*HI-*Xho*I human genomic fragment that contains the $C_{\alpha 1}$ gene subcloned in pBR322 and was subcloned from a Charon 28 phage that was donated by J. Ravetch et al (Harvard University, Cambridge, MA).[17] Recombinant probes for the human light chain Ig gene segments C_λ and J_κ-C_κ were donated by P. Leder. The C_λ probe is a 5.0-kb *Eco*RI-*Hind*III human genomic fragment that is also subcloned in pBR322.[18] The J_κ-C_κ probe is a 2.5-kb *Eco*RI fragment in pBR325.[19] The TCR gene probe is a β-TCR cDNA clone called JUR-beta 2, subcloned in pBR322 and donated by Dr. T. Mak (University of Toronto).[20]

Probe DNAs were labeled with $[^{32}P]$ dCTP (deoxycytidine triphosphate) by nick translation.[14] Hybridization and washing were essentially those described by Wahl et al.[21] After washing, the hybridized blots were autoradiographed using Kodak XAR-5 film and intensifying screens at −70°C for four to 14 days.

RESULTS

All patients were male and ranged from 53 to 79 years of age. Six patients had IgGκ myeloma, two had IgAλ myeloma, and one had IgGλ myeloma (Table 1). Three patients were in stage IIA; three, IIIB; two, IIIA; and one, IA at diagnosis and IIIB at relapse (patient no. 6, Table 1). No patient had obvious circulating plasma cells on microscopic examination of their peripheral blood.

The results of Southern blot analysis with antibody and β-TCR gene probes are summarized in Table 1. Seven of nine patients showed clonal antibody gene rearrangements in PBLs identical to those seen in their respective marrow plasma cells. In all six patients with IgGκ myeloma, this was demonstrated by identification of rearranged light-chain genes and/or heavy-chain genes. In one of two IgA patients, a rearranged light-chain band was detected, whereas only germline DNA was found in the other. In the one patient with IgGλ myeloma, hybridization with the J_H probe only revealed germline DNA.

The two patients with only germline DNA in their PBLs (patients no. 8 and 9), had clearly detectable rearranged Ig bands in their marrow plasma cells. Clinically, they had progressive symptomatic myeloma and were in Durie-Salmon stage IIA and IIIA. The seven patients with clonally rearranged Ig genes in PBLs were in stage IIA (two patients), IIIA (one patient), and IIIB (four patients). Thus, there was no correlation between clinical stage and DNA analysis in this small patient sample. However, one patient, (patient no. 6) did not show a new rearranged band in PBLs at the time of diagnosis when he was in stage IA, but at relapse when he was in stage IIIB, his PBLs contained clonally rearranged DNA (Fig 1). The germline J_H band is approximately 18-kb, and marrow plasma cells, at diagnosis and relapse, show a rearranged band at 13 kb. This rearranged band is only present in PBLs at relapse (Fig 1).

No patient demonstrated clonal β-TCR gene rearrangements in the PBL or plasma cell preparations.

DISCUSSION

The aim of the present study was to investigate whether significant numbers of peripheral blood lymphocytes are part of the malignant clone in multiple myeloma. The detection of clonal Ig and TCR gene rearrangements has been used to demonstrate the clonal origin of other B and T cell–derived tumors.[22-24] We have used these same gene probes to demonstrate that clonal antibody gene rearangements but not TCR gene rearrangements occur in the PBLs of most patients with multiple myeloma. These results indicate that peripheral blood B lymphocytes but not T lymphocytes are part of the malignant clone in multiple myeloma.

These data confirm the work of other investigators who demonstrated peripheral blood monoclonal B cells by either abnormal surface membrane κ/λ light-chain ratios or positive surface immunofluorescence with antiidiotypic reagents.[2-5,25,26] However, these results contradict those of Pilarski et al,[9] King and Wells,[7] and Gobbi et al[8] who failed to find monoclonal B lymphocytes in the peripheral blood of myeloma patients. Pilarski et al[9] studied only three patients in remission and used antiidiotypic reagents. In our study, we only studied patients with active disease. It is interesting to note that the patient with the lowest tumor burden at diagnosis (patient no. 6) only demonstrated involvement in the peripheral blood after the development of clinical relapse with a marked increase in tumor burden. King and Wells[7] studied two patients with active myeloma but with fairly small serum M spikes and two patients in clinical remission.

Table 1. Clinical Characteristics and Southern Blot Analysis

Patient No.	Isotype	Antibody Genes in PBLS			β-TCR Genes in PBLs and Plasma Cells
		Heavy Chain			
		Constant Region	J_H	Light Chain	
1	Gκ	R	R	R	ND
2	Gκ	ND	ND	R	G
3	Gκ	R	R	R	G
4	Gκ	ND	R	R	G
5	Gκ	ND	R	R	G
6	Gκ				
	At diagnosis	G	G	G	G
	At relapse	R	R	R	G
7	Aλ	ND	ND	R	ND
8*	Aλ	G	G	G	ND
9*	Gλ	ND	G	ND	G

Abbreviations: R, rearranged DNA identical to bone marrow plasma cells; G, germline or unrearranged DNA; ND, not done.

*Both these patients demonstrated antibody gene rearrangements in marrow plasma cells.

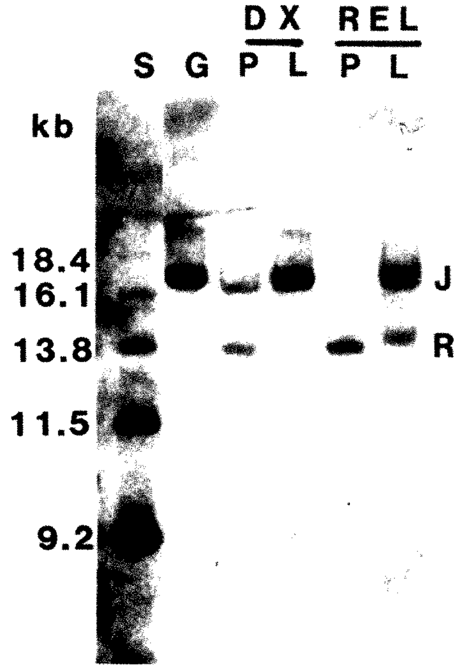

Fig 1. PBL and plasma cell DNA blot hybridization with IgJ$_H$ probe in patient no. 6. All lanes were loaded with a total of 10 μg of *Bam*HI-digested DNA from PBLs, plasma cells, or granulocytes. S, concatemerized plasmid DNA (monomeric length, 2.3 kb) used as a molecular size standard; G, granulocyte DNA, a germline control; P, bone marrow plasma cell DNA; L, PBL DNA; DX, at diagnosis; REL, at relapse; J, germline J$_H$ band; R, rearranged J$_H$ band.

These investigators used a rosette assay to detect idiotype-bearing cells after vigorous washing and failed to demonstrated PBLs bearing an endogenous idiotype when using this technique. This negative result may also reflect the low tumor burden of their patients and the insensitivity of this assay. Gobbi et al[8] used pokeweed mitogen–stimulated peripheral blood lymphocytes from multiple myeloma patients to demonstrate the polyclonality of these cells by using κ/λ ratios. However, a small but significant number of monoclonal cells may not be detected by this technique. It is also possible that the malignant PBLs may not respond to mitogenic stimulation. In contrast to the aforementioned techniques, Southern blot analysis is exceptionally sensitive. Most investigators estimate that as low as a 1% involvement of a cell mixture can be identified by this technique.[27,28]

In our study, we have not shown clonal TCR gene rearrangements in any of our patients. These results would suggest that clonal T cells do not exist in multiple myeloma as has been reported by other workers.[6] However, these investigators used antiidiotypic antisera to demonstrate T cell involvement in a single patient with myeloma. It is well known that there is marked expansion of T cells that bear Fc receptors for the idiotype,[29,30] and these "clonal" T cells were probably T cells with idiotype bound to their Fc receptors.

The common acute lymphoblastic leukemia antigen (CALLA) has been demonstrated on the surface of bone marrow cells in patients with myeloma.[31,32] Because CALLA is normally thought to be present on B lymphoid cells during early stages of differentiation, these data suggest an oncogenic event in myeloma occurring in similar early precursor cells. The presence of pre-B lymphoid cells that express homologous idiotype in two patients with IgA myeloma[33] also supports this notion. We are presently using antibody gene analysis to determine whether earlier stages in B cell differentiation have clonal expansion of cells.

Correlation of Chromosome Abnormalities With Histologic and Immunologic Characteristics in Non-Hodgkin's Lymphoma and Adult T Cell Leukemia-Lymphoma

By the Fifth International Workshop on Chromosomes in Leukemia-Lymphoma

To correlate cytogenetic findings with histology and immunophenotype, 260 newly diagnosed patients with non-Hodgkin's lymphoma (NHL) and 31 with adult T cell leukemia/lymphoma (ATL) were studied at the Fifth International Workshop on Chromosomes in Leukemia-Lymphoma. Clonal chromosome abnormalities were found in 85% of cases of NHL and in all cases of ATL. The most significant associations of histology with cytogenetics involved the 8q24 and 14;18 translocations. Of 23 NHL patients with an 8q24 translocation, 20 (87%) had small noncleaved cell (SNC) lymphoma. Of 57 NHL patients with a t(14;18)(q32;q21), 37 (65%) had a follicular lymphoma, and at least 13 others (23%) had a diffuse lymphoma of follicular center cell origin. Five others including two who also had an 8q24 translocation had SNC lymphoma; tumors in these patients lacked the monomorphic features seen in those with only an 8q24 translocation. The most striking associations of immunology with cytogenetics involved rearrangements of 14q11-13, abnormalities of 1p, trisomy 3, and trisomy 12. Abnormalities of 14q11-13 were correlated with T cell disease. Among 138 NHL and 24 ATL cases that lacked involvement of 8q24, t(14;18), or rearrangements of 14q11-13, abnormalities of 1p and trisomy 3 were significantly associated with the T cell phenotype ($P < .01$) and trisomy 12 with the B cell phenotype ($P < .01$). No karyotype difference was found between Japanese ATL and non-Japanese T cell lymphomas except that +3 occurred more often in the former ($P = .06$). Although the 8q24 translocations in 23 patients were distributed relatively equally among geographic regions (United States, ten; Europe, ten; Japan, three), the t(14;18) in 57 patients was much less frequently seen in Japan than in the other parts of the world (United States, 31; Europe, 21; Australia, four; Japan, one). Thirty-nine chromosome bands had breaks in five or more cases; a number of protooncogenes and genes related to lymphocyte function located in these bands are likely to be involved in the development of lymphoma. Thus, besides confirming the close association of particular chromosome abnormalities with histology, we have identified a number of new associations that merit molecular analysis.

DATA ON CHROMOSOME ABNORMALITIES in non-Hodgkin's malignant lymphoma (NHL) are accumulating rapidly, and some of them have been correlated with specific histological and immunologic phenotypes.[1-9] However the varying histologic classifications used in different institutions have posed a serious problem in correlating specific abnormalities with histology. Moreover, the complicated chromosome abnormalities often observed in lymphoma have sometimes resulted in different interpretations of the same abnormality. Finally, possible geographic or racial differences in the incidence of various chromosome abnormalities have prevented previous studies by single institutions from showing the whole spectrum of the chromosome patterns in lymphoma.

Although all preceding Workshops on Chromosomes in Leukemia had dealt with the correlation between the chromosome pattern and clinical features in leukemia,[10-13] the Fifth Workshop (see Appendix 1) considered the chromosome abnormalities present in NHL and in adult T cell leukemia-lymphoma (ATL) prevalent in southern Japan.[14] This report describes correlations between chromosome abnormalities and the histological and immunologic aspects of lymphoma. Only cases with cytogenetic and histologic studies on the same tumor tissue obtained before any antineoplastic therapy were accepted.

Analysis of the workshop data not only confirmed the importance of certain specific chromosome abnormalities such as the 8q24 translocations and the translocation between 14 and 18 but also indicated the morphological spectrum of cells with such abnormalities by using the working formulation (WF).[15] The data confirmed the significance of the abnormalities in the proximal long arm of chromosome 14 in T cell lymphomas including ATL and trisomy 12 in B cell lymphomas. Furthermore, this analysis provided further evidence for the involvement of the short arm of chromosome 1 and trisomy 3 in T cell lymphomas. A number of recurring chromosome breakpoints involved the location of known protooncogenes or lymphocyte-specific genes; others were found in bands not presently associated

with such genes and thus identified other regions that may be important in the genesis of specific lymphomas.

MATERIALS AND METHODS

Cases of NHL with banded chromosome analysis on lymph node or other tumor tissue performed before therapy and before the end of 1983 were collected before the workshop. Karyotypes and histology slides on each case were submitted along with detailed clinical data. Cases with ATL were collected from some Japanese centers; for ATL, patients with chromosome studies only on blood or bone marrow were accepted if they were positive for anti–ATL-associated antigen (ATLA) antibody.

The submitted karyotypes were initially reviewed at the workshop headquarters in the Saitama Cancer Center (The karyotypes were reviewed at the headquarters before the workshop by R. Abe, Y. Kaneko, N. Maseki, M. Sakurai, J. Takeuchi), and again by the preworkshop karyotype review committee (R. Abe, S. Abe, G. Alimena, D.C. Arthur, R. Berger, O.M. Garson, A. Hagemeijer, D.K. Hossfeld, Y. Kaneko, and F. Mitelman), which finalized the interpretations. Karyotypes were designated according to the ISCN (International System for Human Cytogenetic Nomenclature), 1978.[16] Clonality of the abnormalities was determined by using criteria of the First Workshop.[10] All clinical, pathological, and cytogenetic data were computerized, and processed data were made available for the workshop.

The histology slides, usually accompanied by slides of cytology, were reviewed individually by five hematopathologists (C. Berard, G. Frizzera, M. Kikuchi, K. Nanba, and T. Suchi) who then met before the workshop and finalized the diagnosis according to the WF (Table 1).[15] For this workshop, diffuse lymphomas with medium-sized cells exhibiting nuclear polymorphism were also included in category E, ie, malignant lymphoma (ML), diffuse, small cleaved cell (DSC). Category J, ML, small noncleaved cell (SNC), was divided into three subcategories, ie, Burkitt, non-Burkitt polymorphic, and not otherwise specified (NOS). The results of the pathological analysis have been reported elsewhere in detail.[17] For ATL, only cases for which histology slides from tumor tissue were submitted were included within the NHL group; ATL cases for which only bone marrow and/or blood smears were available were considered separately.

Each institution studied the immunologic phenotype of lymphoma cells according to its usual procedure, using cell suspensions and/or tissue sections. Sheep erythrocyte rosette formation and surface immunoglobulin determination were generally applied. The monoclonal antibodies used varied among institutions, but the Leu or OKT series were commonly used to identify T cells and B1, B2, BA-1, and BA-2 to identify B cells.

Table 1. A Working Formulation of NHL for Clinical Usage

F. Diffuse mixed (DM)	

*For the workshop, diffuse lymphoma with medium-sized cells exhibiting nuclear polymorphism were included in this category.

†This category was subdivided into monomorphic (Burkitt's), polymorphic (non-Burkitt's), or NOS.

‡This category includes composite, mycosis fungoides, histiocytic, and extramedullary plasmacytoma.

Data from Non-Hodgkin's Lymphoma Pathologic Classification Project.[15]

Statistical analysis was made by the chi-square or Fisher's exact test.

RESULTS

Two hundred sixty adequately studied cases of NHL were accepted for analysis. There were 149 males and 111 females, including 202 whites, seven blacks, and 51 Orientals. The ages ranged between 1 and 86 (median, 56 years). In addition, 31 Japanese (Three ATL cases submitted from Kochi, Japan, by Y. Shiraishi are included in the study) patients (21 males and ten females; ages, 29 to 76; median, 54) with ATL whose karyotypes were analyzed from blood were also accepted. Because of the short observation period (a median follow-up of 9 months), data on survival are not included in this report.

Correlation of Karyotype With Histologic and Immunologic Features in NHL and ATL

Modal chromosome number. Two hundred twenty-two (85%) of the 260 patients with NHL and all 31 patients with ATL had clonal chromosome abnormalities. Thus, 38 (15%) of the NHL cases had a normal karyotype in cells obtained from the tumors. Modal chromosome numbers of the lymphomas by histologic category are shown in Table 2. Among 253 NHL and ATL cases with abnormalities, 92 (36%) had a modal chromosome number of 46. The second most frequent modal number was 47 (61 cases), followed by 48 (31 cases), 49 (16 cases), and 50 (nine cases). Only 13 patients had a modal number between 51 and 61, and ten had a polyploid mode. There were only 21 hypodiploid cases, of which 18 had a modal number of 45. Among the cases with abnormalities, a modal number of 46 was most frequent in SNC (68%), LBL (50%), DSC (57%), and FSC (50%) lymphomas. However, higher modal numbers (47 to 50 chromosomes) were seen in FM (60%), FL (67%), DM (59%), DL (51%), and IBL (54%) histologic groups. Tumors that showed only a normal karyotype were distributed among virtually all histological subtypes, but they were most frequent in FSC (28%), DSC (30%), DM (25%), and LBL (38%) lymphomas.

Number of abnormal clones. Table 2 also lists the number of abnormal clones observed by histologic subtype. A single abnormal clone was detected in 207 of the 253 abnormal cases (82%); thus only a single stemline was observed in these tumors.[16] Forty cases showed two clones; except for three cases, the clones were clearly related because they had common cytogenetic changes and the more abnormal clone represented further karyotypic evolution. These tumors therefore had a stemline with one sideline.[16] Of the six tumors that had more than two clones detected, five had some common cytogenetic changes, whereas the other had one clone that lacked changes related to the other clones. Thus for the whole group, there were only four tumors that showed two or more unrelated clones.

Abnormalities in 8q24. Twenty-three (8.8%) of the NHL cases and one of the ATL cases had a translocation involving band 8q24 (Table 3). There were 17 patients with t(8;14)(q24;q32), two with t(2;8)(p11;q24), and two with t(8;22)(q24;q11). In addition to the 21 patients with 8q24

abnormalities involving one of the three chromosomal bands in which immunoglobulin genes are located (ie, 14q32, 2p12 and 22q11),[18] two patients had a translocation involving 8q24 and another chromosomal band. One patient had −8,+der(8)t(8;?)(q24;?), and the other had t(8;11)(q24;q13); these two cases also had a t(14;18). One ATL case had t(8;10)(q24;q22).

Five of the 17 patients with t(8;14)(q24;q32) had this translocation as the only chromosome abnormality, and two others had either only a t(2;8) or a t(8;22) translocation (Table 4); thus 14 of 21 with standard or variant 8q24 translocations had additional chromosome abnormalities (Table 5). The most common additional change was duplication of part of 1q, always including 1q21-32, which was seen

Abbreviations: i(7q), isochromosome of 7q; 6q−, del(6)(q15 or 21 or 23); i(6p), isochromosome of 6p; +18q−, +der(18)t(14;18)(q32;q21); dup(1q), partial trisomy of 1q.

*Includes 17 cases with t(8;14), two cases with t(2;8), and two cases with t(8;22).

†The difference in frequency in t(8q24) compared with t(14;18) was significant, $P < .05$.

in four patients. There were two patients with +12 and one each with −X, +7, a partial deletion of either 6q or 9p, or an unidentified chromosome segment attached to band 1p36.

Of the 23 NHL cases with an 8q24 translocation, 20 (87%) had SNC lymphoma; 11 (55%) of these 20 had SNC, monomorphic (Burkitt) including one with t(8;11)(q24;q13); eight (40%) had SNC, NOS; and one patient with −8,+der(8)t(8;?)(q24;?) had SNC, polymorphic (non-Burkitt). One patient each with a t(8;14) exhibited DL, IBL, or FSC lymphoma; thus the 8q24 translocations were significantly associated with SNC histologies ($P < .01$). Seven cases with an 8q24 translocation as the sole abnormality showed an SNC morphology. Immunologic phenotyping were available for 15 cases; all except one ATL case were B cell (Table 3).

14;18 translocation. Fifty-seven (21.9%) NHL cases had a t(14;18)(q32;q21), the most common abnormality found in the workshop (Table 3). Five cases had only the translocation (Table 4), whereas 52 (91%) had additional abnormalities (Table 5). The common numerical chromosome changes were +7 (seen in 15 patients), +X (eleven patients), +12 (seven patients), +21 (six patients), and a missing sex chromosome (in eight patients). Two patients had a +7, and two others had a +12 as the only changes; one other had both a +7 and a +12 without other additional changes. Of the 28 males with a t(14;18), nine had numerical sex chromosome abnormalities (+X in five, a mosaicism of +X/+Y in one, −Y in three); of the 29 females, 12 had numerical sex chromosome abnormalities (+X in five, −X in seven). Thus, an extra X was seen with equal frequency in both sexes, whereas an extra Y was rare. The loss of an X in females was more frequent than loss of a Y in males. Among the structural changes, an extra derivative 18q− chromosome consisting of most of chromosome 18 and the terminal segment of chromosome 14 was seen in six patients; this chromosome appeared to be a duplication of the 18q− chromosome. A partial deletion of 6q was seen in six patients; a partial deletion of 4p was seen in four; and an isochromosome of 6p or 7q or a 1p+ chromosome consisting of chromosome 1 with an unknown segment attached to band 1p36 each were noted in three patients. No patient had a duplication of 1q.

In general, additional abnormalities were more common in patients with a t(14;18) than with a t(8;14). Thus the frequency of trisomy 7 or isochromosome 7q and of trisomy X was significantly higher in the former than in the latter patients ($P < .05$). The exception was the 1q duplication, which was only seen in t(8;14) patients ($P < .05$).

Cases with the 14;18 translocation were significantly more frequently ($P < .01$) FSC (26%) and follicular, mixed, small cleaved and large cell (FM) (33%) lymphomas. Except for seven diffuse lymphoma cases in which the origin of the lymphoma cells was not specified, all others with this translocation were of follicular center cell origin. Of the five cases with no additional abnormalities, two had FSC, one had FM, and the other two had DSC lymphomas. Thus, cases with a simple t(14;18) were not invariably accompanied by a follicular histologic pattern.

Most cases (37 of 39, 95%) with a t(14;18) for which immunophenotyping data were available were B cell, but two (5%) were T cell (Table 3). One patient with a T cell phenotype had an FM lymphoma, and the other had an IBL lymphoma.

Abnormalities of 14q11-13. Six (2.3%) NHL cases and six (19%) ATL cases had abnormalities involving the proximal portion of 14q, ie, 14q11-13 (Table 6). Of these 12 cases, four had an inv(14)(q11q32), and one had a t(14;14)(q11;q32); both abnormalities showed the same breakpoints. Two patients had a del(14)(q11) as well as a partial deletion of the other 14q involving either bands 14q11 to q13 or 14q13 to q24. Five other patients had balanced or unbalanced translocations involving 14q11 or 13 and other chromosomes. Only one of the 12 patients with a 14q11-13 abnormality had an inv(14) as the sole abnormality.

Eleven patients had additional chromosome abnormalities; among the numerical abnormalities, +8, +15, +21, and −X were seen in two patients each and +2, +3, +9, +11, +16, and +19 in one each. The only recurring structural change was a 1p+ chromosome with an unknown chromosome segment attached to band 1p36 in three patients.

Five of the six NHL patients with abnormalities involving 14q11-13 had T cell–specific morphologies, ie, LBL, convoluted cell (two patients), diffuse medium-sized cell lymphoma with nuclear polymorphism, DM, or IBL, polymorphous (one patient each). The sixth patient had IBL. The 14q11-13 abnormality was not seen in FSC lymphoma. All cases with a 14q11-13 abnormality for which the immunologic data were available showed a T cell phenotype.

Trisomy 3. Of the 260 cases with NHL, 14 (5.3%) had a +3 (Table 3). In two it was the only abnormality (Table 4), and in a third case one clone had only +3 whereas other clones had +3 and additional abnormalities. In addition to a +3, three also had a t(14;18), one had a 14q11-13 translocation, and the other eight had various other abnormalities. Eight cases with ATL also had a +3, in one as a sole abnormality. None of the other seven had 14q11-13 abnormalities.

The three NHL cases with a +3 as the sole abnormality had a DM lymphoma. Three of the eight cases having a +3 but none of the three common chromosome abnormalities (8q24, t(14;18), and 14q11-13 abnormalities) also had a DM lymphoma. Thus, cases with +3 primarily had DM lymphoma ($P < .05$). Three cases with +3 and a t(14;18) had FM, DM, or IBL lymphoma, and another case with a +3 and an inv(14)(q11q32) had a diffuse medium-sized cell lymphoma with nuclear polymorphism. Excluding the four cases of +3 with a t(14;18) or a 14q11-13 abnormality, 11 NHL and ATL cases had a T cell phenotype, and only two NHL cases had a B cell phenotype. Thus, +3 cases were found significantly more often with a T cell than a B cell phenotype ($P < .01$) (Table 7).

Trisomy 12. Twenty-two (8%) of the NHL cases had a +12 (Table 3). Two had a +12 as a single abnormality, and another patient had one clone consisting of only a +12 and a related clone with an additional abnormality. Twenty of these 22 (91%) had other structural and/or numerical abnormalities. Thus, seven had a t(14;18)(q32;q21), and two had a t(8;14)(q24;q32); none had a 14q11-13 abnormality.

The three cases with only a +12 showed SL morphology, and eight of the 22 cases had DL lymphoma. Thus, there was some association of +12 with the SL and DL categories of NHL. None of the cases with ATL or lymphomas histologically categorized as T cell lymphoma had a +12. Lymphoma cells of all 13 cases having +12 for which immunologic data were available showed a B cell phenotype.

Abnormalities of 1p. Twenty-eight NHL and six ATL cases had abnormalities of chromosome 1p. Of the NHL cases, one had a t(8;14), seven had a t(14;18), two had a 14q11-13 abnormality, and 18 had other abnormalities (Table 7). Two of the ATL cases had a 14q11-13 abnormality. Of the 34 NHL and ATL cases, the breakpoint occurred in 1p36 in 17, in 1p34 in four, in 1p31-32 in seven, and between 1p22 and 1p11 in six. Thus, the breaks clustered in 1p31-36. Among the 34 cases, the other involved chromosome was identified in only one case with a complex rearrangement. The most frequent change was a translocation of an unknown chromosome segment to 1p36.

Eighteen cases had a 1p abnormality without the three common abnormalities. Fourteen had a diffuse lymphoma, most commonly IBL (seven patients), but the association was not statistically significant. Where immunologic data were available, seven of the NHL cases and all ATL cases showed a T cell phenotype; only three of the NHL cases showed a B cell phenotype. Thus, a 1p abnormality significantly more frequently had a T cell rather than a B cell phenotype ($P < .01$) (Table 7).

Other abnormalities of 14q32. In NHL, 14q32 translocations involving a chromosome band other than 8q24,

*Only numerical changes or locations of structural abnormalities (deletions, translocations, derivative chromosomes) that were present in more than eight evaluable cases.

†Significantly correlated with the immunologic phenotype at the .01 level.

18q21, or 14q11-13 were found in 38 cases (Table 7); the translocation partner was known in only six of them, and they were all different (1q25, 2p21, 2p15, 8q22, 11p11, and 11q13). Five ATL cases had a 14q32 translocation; three had a der(14)t(14;?)(q32;?), and the other two had either a t(5;14)(q22;q32) or a t(10;14)(q21;q32).

These 38 cases were randomly distributed among all histologic categories. Of the 19 NHL cases with the 14q32 translocation and immunologic data, 12 showed a B cell and seven a T cell phenotype.

Abnormalities 6/6q. Forty-three (17%) of the 260 cases with NHL had a deletion of the long arm of chromosome 6, either a del(6q) (37 cases) or an isochromosome of 6p, i(6p), which leads to loss of the entire long arm (six cases). The deletion was thought to be terminal in 26 cases (involving two different deletions in one case), interstitial in eight, both in one, and undefined in two cases. The distinction between the loss of all of the chromosome distal to the breakpoint (terminal deletion) and loss of some intervening segment with unequivocal retention of the telomeric portion (interstitial deletion) may be unclear. Although molecular analysis of other chromosome deletions, eg, del(5q) and del(20q), has often shown them to be interstitial, in this report, deletions without a definite q terminal region were classified as terminal. Two cases had a del(6)(q23) or a del(6)(q23q25) as the single abnormality (Table 4), and 41 (95%) had other numerical and/or structural abnormalities including a t(14;18) (eight cases), an 8q24 translocation (one case), and a 14q11-13 abnormality (one case). The breakpoint was 6q11-14 in five cases, 6q15 in 11, 6q21 in 14, 6q23 in 10, 6q24 in one, and 6q25 in five. No common chromosome segments were deleted. Deletion of 6q was also seen in seven cases with ATL, four interstitial and three terminal. The breakpoint was 6q15 in four cases, 6q21 in four, 6q23 in one, 6q25 in two. Six of the seven cases had lost a part of band 6q21.

The pathological diagnoses of the lymphomas having a del(6q) or an i(6p) included all categories of the WF except DSC. Only seven of the 43 were diagnosed as follicular lymphoma. No significant correlations were noted between the breakpoint or the size of the deleted segment of 6q and the histologic or immunologic type of NHL.

Other chromosome abnormalities. Thirty-one (12%) NHL and two ATL cases were found to have abnormalities of the long arm of chromosome 11. Only one of the NHL cases had an 11q abnormality, which was a del(11)(q14q23), without other changes. Five NHL cases also had a t(14;18), and one had a t(14;18) and an 8q24 translocation involving 11q13; none of them had a 14q11-13 abnormality. The 11q abnormalities seen in NHL included balanced translocations (five), unbalanced translocations (13), terminal deletions (six), interstitial deletions (five), an undefined deletion (one), and an isochromosome of 11q (one). Three of the five reciprocal translocations had a break in 11q11-13, and the other two had 11q21 and 11q23 breakpoints; the other chromosome involved was nos. 2, 3, 8, 9, and 19. Nine of the 13 unbalanced translocations had a break in 11q23-25, and two each had a break in 11q11-13 or 11q14-22. Of 11 defined terminal and interstitial deletions, all had a break in 11q23-25, four also had a break in 11q14-22, and none had 11q11-13 breaks. Thus in the great majority of deletions and unbalanced translocations (20/26) breakpoints clustered in 11q23-25. All interstitial deletions included bands 11q21-23. The unbalanced translocations led to a terminal deletion of q25-qter in five cases, of q23-qter in three, and q11-q15 in the remainder. Thus, nine cases with an unbalanced translocation and six with a terminal deletion lost the segment distal to either 11q23 or 11q25. Two ATL cases had either an unbalanced 11q25 translocation with an unknown donor or an 11q23 terminal deletion.

There was no significant correlation between the type or extent of deletion and histology. One case with a DM lymphoma from an ATL endemic area of Japan and two cases with ATL showed a T cell phenotype; the other 14 NHL cases (excluding those with the three common abnormalities) with immunophenotyping data showed a B cell phenotype.

Three NHL and one ATL case had a translocation or a deletion involving 7q35-36, a location where the T cell β chain receptor gene has been mapped. One of the three NHL cases showed a T cell phenotype, and the other two showed B cell or non-T, non-B phenotypes. Chromosome abnormalities involving 7p15, a location where the T cell γ chain receptor gene has been assigned, were seen in two cases with NHL and one with ATL. One of the two NHL cases showed a T cell phenotype, and immunophenotyping was not done in the other. Chromosome abnormalities involving a break in 6p23 were seen in two NHL cases with T cell phenotype (DM and DL) and one ATL case; one other case with a deletion of 6p22-24 had a B cell phenotype and SNC histology.

Twenty different abnormalities were seen as the only chromosome changes in 31 of the 291 NHL and ATL cases; ten of these have been described above. The karyotypic abnormalities as well as the histology and immunophenotype of these 31 cases are listed in Table 4.

Cases with unrelated clones. Four patients had at least two apparently unrelated clones in their tumors. Two of these patients had one clone with a t(14;18)(q32;q21) plus other abnormal chromosomes (modal numbers 54 and 90), whereas the other clone had a simple abnormality, either −1,+der(1)t(1:?)(q12;?) or −13,+der(13)t(13;?)(q22;?). Both patients had an FM lymphoma, but immunophenotyping was uninterpretable. One other patient had four clones in his DM lymphoma; three of them had 47 or 48 chromosomes with a trisomy 3, but the fourth clone had an unrelated karyotype with 51 chromosomes without a +3. In this patient again, the immunophenotype was unknown. The last patient had hyperdiploid and tetraploid clones with no common chromosome changes; the tumor was IBL lymphoma, polymorphous, with a T cell phenotype.

Correlation of Histology and Immunology With Karyotype

Tables 3 and 7 show the relationship between the chromosome abnormalities and the histology and immunophenotype of the lymphomas. The largest number of NHL patients (42) had a large cell IBL type, and the smallest number (six) had an FL type.

Karyotypes in SNC lymphomas. Of the 32 SNC lymphomas, 15 were classified as NOS, 13 as monomorphic (Burkitt's), and the other four as polymorphic (non-Burkitt's) (Table 3). In the first group, seven had an 8q24 translocation, three had a t(14;18), one had both an 8q24 translocation and a t(14;18), three had other abnormalities, and one had a normal karyotype. In the Burkitt's group, 11 had an 8q24 translocation, two had other abnormalities, but none had a t(14;18). In the third group, one had a t(14;18), and three had other abnormalities, but none had an 8q24 translocation. While all five patients with a t(14;18) (including two with both a t(14;18) and an 8q24 translocation) were more than 40 years old, those with an 8q24 translocation but no t(14;18) were generally young, with a median of 11 years.

Karyotypes in follicular (FSC, FM, and FL) lymphomas. When all 64 patients with follicular lymphoma (FSC, FM, or FL) were considered, ten had a normal karyotype, and 37 (58%) had a t(14;18) (Table 3). Among the 17 patients with chromosome abnormalities but without a t(14;18), one had a t(8;14)(q24;q32), and seven had −14,+der(14)t(14;?)(q32;?); thus, the latter tumors contained a 14q+ chromosome with an unidentified donor chromosome. Nine cases had various other chromosome abnormalities.

Immunophenotypic data. One hundred fifteen cases had the immunologic phenotype of the lymphoma cells determined only on tumor cells in suspension, eight only on tumor tissue sections, 84 on both, and four on unknown types of material. One hundred twelve cases were shown to be a B cell, 34 to be T cell, and eight to be non-T, non-B phenotype; the data were uninterpretable in 57 cases. In ATL, 29 patients had immunophenotyping on malignant cells in the blood, and all were proved to have a T cell phenotype. Thus, 146 cases with lymphoma and 29 cases with ATL exhibited either B or T cell phenotypes; the association of the immunologic phenotype and specific chromosome changes have been described in detail in the preceding sections and are summarized in Tables 3 and 7.

Lymphomas in patients under 20 years of age. Thirty-three (13%) of the 260 NHL patients were under 20 years of age. Of these, 15 had SNC lymphomas, 13 had LBL, three had IBL, and two had DL. Twelve of the 15 SNC patients had an 8q24 translocation, two had a 14q+ chromosome with an unknown chromosome segment at band 14q32, and one other had a normal karyotype. Nine of the 13 LBL patients had chromosome abnormalities, two with a 14q11-13 and three with 6q-abnormality; these abnormalities were also seen in T cell lymphomas of various histologies in adults. Four of the five patients with a 14q11-13 or 6q-abnormality showed a T cell phenotype.

Geographic Differences in Karyotypic Features

8q24 v 14;18 translocations. The geographic distribution of the karyotypic pattern in NHL was examined; attention was focused on the two most frequent specific translocations (Table 8). Thus, of the 23 patients with an 8q24 translocation, ten were American, ten European (both all white), and three Japanese; the proportion of all patients in each geographic area was 10%, 10%, and 6%, respectively. Of the 57 patients with a t(14;18), 31 were American (one black), 21 were European, four were Australian, and only one was Japanese; the proportion of all patients in each geographic area was 32%, 21%, 31%, and only 2%, respectively. Thus, the 8;14 translocation showed an even racial or geographic distribution, but t(14;18) was more frequent in the United States and Europe (or whites) than in Japan (or Japanese) ($P < .01$).

Japanese ATL v non-Japanese T cell lymphomas. The chromosome pattern of neoplastic cells from 38 patients with T cell lymphoma/leukemia in the ATL endemic area of Japan was compared with that from 21 patients with T cell lymphoma outside Japan, excluding the two patients with a t(14;18) and T cell phenotype. The Japanese patients included 31 ATL and seven others whose lymph nodes had a T cell phenotype. As shown in Table 9, 14q11-13 abnormali-

Table 8. Correlation of Chromosome Abnormalities in NHL With Geographic Region

	Cases With NHL				
Chromosome Abnormality	USA	Europe	Australia	Japan	Total
8q24 translocations	10*	10*		3	23
t(14;18)	31	21	4	1	57
14q11-13 abnormalities	2	1		3	6
Others	42	53	6	38	139
Normal	12	16	3	6	37
Total	96†	100†	13	51	260†

*One case had an atypical 8q24 translocation and a t(14;18).

†The total is less than the simple addition of the figures above because two cases with an 8q24 translocation also had a t(14;18).

Table 9. Chromosome Abnormalities in Japanese ATL and Non-Japanese T Cell Lymphomas

Abnormality	Japanese ATL* (n = 38†)	Non-Japanese T Cell Lymphomas (n = 21‡)
14q11-13	8	3
6q15-21	9	6
14q32	7	3
6p21-23	4	0
1p32-36	6	4
10q22-26	5	0
9p11-24	5	1
+3	9	1
5q11-13	6	0

*The cases were submitted from Nagasaki, Kochi, and Okayama. All 38 cases were submitted as having ATL from these centers, of which seven cases whose histology slides were also submitted were included in the 260 NHL cases and the others not accompanied by such slides were accepted as one of the 31 ATL cases.

†Includes one case with a normal diploid tumor.

‡Includes four cases with a normal diploid tumor and excludes two cases with a t(14;18) and T cell phenotype.

ties were seen in eight Japanese patients and in three non-Japanese patients. Three of the former patients and one of the latter had an inv(14)(q11q32), and two of the former had a del(14)(q11) and/or a del(14)(q11q13). Deletions of 6q having breakpoints in 6q15 or 6q21 were seen in nine Japanese and in six non-Japanese patients. Abnormalities of 14q32 and lp were seen equally in both groups of patients. The most striking difference was the frequency of +3 and of 5q11-13 abnormalities. A +3 was seen in nine Japanese and in only one non-Japanese patient ($P = .06$), and 5q11-13 abnormalities were found in six Japanese and in none of the non-Japanese patients ($P = .06$).

Recurrent breakpoints. Thirty-nine chromosome bands were the sites of five or more independent breaks; the number of breaks is listed in Table 10. Some of these breakpoints were known locations of cellular oncogenes and of genes important in lymphocyte functions.[18-24] The breakpoints clustered to regions such as 1p32-36, 6q13-25, and 11q13-25, each of which contains several protooncogenes; other breakpoints such as 14q32 and 14q11 are the sites of lymphocyte-related genes.

DISCUSSION

In this paper, we report results obtained at the Fifth International Workshop on Chromosomes in Leukemia-Lymphoma and focus specifically on the correlation between the chromosome abnormalities and the histologic diagnosis or the immunologic phenotype of the lymphomas. Although the study was retrospective and certain limitations existed, especially in the assessment of the incidence of various chromosome abnormalities, the centralized exhaustive review of the karyotypes and the consensus pathologic diagnosis using slides submitted from the same tumor were unique to this workshop. The cytogenetic and pathologic data obtained from this very large number of lymphoma cases appear to show a clear correlation between these two parameters, especially with regard to 8q24 translocations, t(14;18), and rearrangements of 14q11-13. In addition, cases with ATL submitted from a number of Japanese centers permit the comparison of the karyotypic features between this well-known endemic T cell disease and the T cell lymphomas seen in other parts of the world.

*Breakpoints observed in five or more cases are listed.

†IGK, Immunoglobulin κ chain gene; TCRα, T cell receptor α chain gene; IGH, immunoglobulin heavy-chain gene; IGL, immunoglobulin λ chain gene. Data are from various sources.[18-24]

Modal Chromosome Numbers

The distribution of the modal chromosome numbers were similar to those reported earlier in lymphoid malignancies including acute lymphoblastic leukemia and lymphoma.[3-5,12] When the histologic category was considered, hyperdiploid modal chromosome numbers were seen more frequently in cases with FM, FL, and DL lymphomas. These findings were related to the fact that the cells with a t(14;18) had a propensity to acquire additional abnormalities. Rather fewer cases with SNC or LBL had a hyperdiploid modal chromosome number, which seemed to reflect the rare occurrence of additional abnormalities in the t(8;14) and LBL.

Correlation of the Karyotype With Histological and Immunologic Features in Lymphoma

The workshop has confirmed the correlation of histology in B cell lymphomas with the karyotype, namely, 8q24 and t(14;18) abnormalities. Except for the two cases with atypical 8q24 translocations and t(14;18), none had more than one of the frequent abnormalities. The 8q24 translocation particularly showed a good correlation with morphology, ie, with SNC, a majority of the patients being subclassified in Burkitt's type. The cases with an 8q24 translocation but with a histology other than the typical SNC had a histology closely related to SNC. The t(14;18) was primarily associated with follicular lymphomas (FSC or FM). Many of those with a t(14;18) but with a nonfollicular pattern showed a histology of follicular center cell origin.

However, the t(14;18) was seen in five patients with SNC lymphoma, including two with both t(14;18) and 8q24 translocations. These cases were classified in the NOS or the polymorphic (non-Burkitt's) subcategory. In contrast to the young age of patients with an 8q24 translocation, these five patients were all older. Thus, these findings suggest that there are two biologically different types of SNC lymphoma and that the one with a t(14;18) arises from a germinal center, whereas lymphomas with a t(8;14) arise from outside the germinal center.

The t(8;14)(q24;q32), when present as the sole abnormality, was always associated with SNC morphology, often being diagnosed as Burkitt's lymphoma. On the other hand, cases with a simple t(14;18)(q32;q21) did not always show follicular morphology. Thus, although three of the five such cases were follicular, the remaining two patients showed a DSC morphology.

Structural abnormalities involving 14q11-13, a location where the T cell receptor α chain gene has been assigned, were associated with various morphologies of T cell lymphoma, ie diffuse medium-sized cell lymphoma with nuclear polymorphism, DM, IBL polymorphous, and LBL, and indicated the importance of the proximal 14q abnormality in the occurrence of both thymic and peripheral T cell lymphoma.

Among numerical abnormalities, +3 and +12 correlated with distinct subtypes of lymphoma, both histologically and immunologically. Thus, +3 was almost always associated with a T cell phenotype and DM lymphoma or ATL. The fact that three cases having a +12 as the single abnormality has SL morphology suggests that SL lymphoma with a +12 is another specific cytogenetic subtype of NHL. Trisomy 12 also correlated with the DL category, all of which showed a B cell phenotype. The biologic importance of +3 and +12 should be the subject of future investigation. Although these trisomies may be directly related to the expression of the immunologic phenotype, they may also be superimposed on some primary unidentified genetic changes. A significant correlation of 1p abnormalities with T cell lymphomas was also established, which suggested that genes related to T cell expression may be located on 1p. Cases with a 6p23 breakpoint and 11q abnormalities seemed to be correlated with T cell and B cell lymphomas, respectively. The significance of these associations is currently unknown.

Uneven Geographical Distribution of Some Lymphomas

Although the 8q24 translocation–associated lymphomas showed an equal racial or geographic distribution, the t(14;18)-associated lymphomas were more common in the United States, Europe, and Australia than in Japan. The uneven distribution of the t(14;18)-associated lymphoma may be related to the fact that follicular lymphoma, which is known to be common in the United States and Europe, is rather rare in Japan.[14]

Although the number of patients examined was small, there seemed to be no difference in the chromosome pattern between ATL from the Japanese endemic area and T cell lymphomas elsewhere. The only exception was an extra chromosome 3, which was seen more frequently in Japan. The only non-Japanese workshop case with a clone with a +3 as a sole abnormality had a DM lymphoma of peripheral T cell origin. This difference may be related to the fact that half of the T cell lymphomas outside Japan were LBL that were primarily composed of malignant lymphoid cells in the thymic stage of differentiation, whereas ATL is believed to be a malignant change of the peripheral T cell. Further support for this interpretation is provided by studies of human T-lymphotropic virus I–positive patients from the Caribbean; the most frequent change observed in four of six patients was a +3.[25]

Recurring Chromosome Breakpoints

One of the most exciting areas in cancer research has developed from the genetic analysis of recurring chromosome rearrangements, especially translocations. Analysis of the t(8;14) in Burkitt's lymphoma has revealed that this translocation results in the juxtaposition of a protooncogene, *c-myc*, at 8q24 and the immunoglobulin heavy (IgH) chain gene at 14q32 (Table 10).[26,27]

Study of the t(14;18) has shown that IgH is involved with a different gene of unknown function called *bcl-2*.[28] More recently, analysis of a t(8;14)(q24;q11) in T cell CLL has revealed a rearrangement analogous to that seen in Burkitt's lymphoma; in T cells, the gene for the α chain of the T cell receptor is moved next to *c-myc*.[29,30] In this workshop report we have presented further evidence for the frequent involvement of certain chromosome regions in recurrent rearrangements, namely, 1p32-p36, 6q13-q25, and 11q13-q25. A number of protooncogenes are located within these same chromosome segments. Based on the aforementioned research, the search for involvement of some of these protooncogenes in the appropriate rearrangements is likely to be productive.

This workshop has provided further evidence that patients with lymphoma can be classified according to the specific chromosome abnormalities present in the tumors and that these patients present group-specific features. Further efforts to define additional cytogenetic groups will help to clarify the histologic characteristics and immunologic phenotypes of the various subtypes of lymphoma. The fact that cases with a normal karyotype were distributed among most histologic groups and about equally between immunologic phenotypes may indicate that in most if not all such cases we were studying the karyotype of the normal rather than the lymphoma cells. Prospective studies will help to find additional recurring abnormalities, to determine further the distribution of various abnormalities among races or geographic regions, and to evaluate the prognostic significance of the karyotype in NHL and ATL.

ACKNOWLEDGMENT

Thanks are due to Tanabe Pharmaceutical Co, Ltd, and Nippon Kogaku Co, Ltd, for providing us with a room for the preworkshop karyotype review meeting or with microscopes for use at the workshop.

APPENDIX 1

The Fifth International Workshop on Chromosomes in Leukemia-Lymphoma was held in Ranzan, Saitama, Japan, October 11 to 15, 1984. The Workshop was organized by M. Sakurai, Y, Kaneko, and N. Kamada. The participants were S. Abe, Sapporo, Japan; G. Alimena, Rome; D.C. Arthur, Minneapolis; C.W. Berard, Memphis; R. Berger, Paris; C.D. Bloomfield, Minneapolis; G. Borgström, Helsinki; A. de la Chapelle, Helsinki; G. Dewald, Rochester, MN; G. Frizzera, Minneapolis; O.M. Garson, Melbourne; H.M. Golomb, Chicago; A. Hagemeijer, Rotterdam, The Netherlands; D.K. Hossfeld, Hamburg, Germany; N. Kamada, Hiroshima, Japan; Y. Kaneko, Ina, Saitama, Japan; M. Kikuchi, Fukuoka, Japan; U. Kristoffersson, Lund, Sweden; S.D. Lawler, London; C. Mecucci, Leuven, Belgium; F. Mitelman, Lund, Sweden; K. Miyamoto, Okayama, Japan; K. Nanba, Hiroshima, Japan; P. Philip, Copenhagen; R. Pierre, Rochester, MN; J.D. Rowley, Chicago; N. Sadamori, Nagasaki, Japan; M. Sakurai, Ina, Saitama, Japan; A.A. Sandberg, Buffalo; T. Suchi, Nagoya, Japan; L. Teerenhovi, Helsinki; H. Van Den Berghe, Leuven, Belgium; and H. Yamamoto, Hiroshima, Japan. N. Maseki, K. Shimamura, R. Abe, J. Takeuchi, M. Ohta, and H. Nagatsuma served as the workshop headquarters staff.

The workshop participants acknowledge the important contributions of their respective collaborating pathologists: M.E.F. Prins, Rotterdam, The Netherlands; J. Rodhain, Brussels-Leuven, Belgium; A. Louwagie, and C. Peeters, Leuven, Belgium; L. Ruco, Rome; K. Franssila, Helsinki; P.M. Banks, Rochester, MN; D. Variakojis, Chicago; and G. Flandrin, Paris; B. Gusterson, London; M. Åkerman, Lund, Sweden.

Precommitted Erythroid Cells Enriched in Cultures of Suboptimally Induced Friend Erythroleukemia Cells

By Enrico DiMambro, Maria Galanti, and Stuart B. Levy

In the presence of suboptimal inducing amounts of dimethylsulfoxide or hexamethylenebisacetamide, a major proportion of uncommitted murine erythroleukemia (MEL) cells was found to be precommitted or primed for commitment, which was demonstrated by their rapid commitment to terminal differentiation when recultured for short periods of time (three to six hours) with fresh inducer. These same cells did not commit if left in the original inducer-containing media or if replated in fresh media without inducer. The two inducers could be interchanged in the priming and postpriming period without affecting the commitment event. However, hemin, an agent that induces hemoglobin synthesis without commitment, showed no ability to enhance commitment of a primed cell population. The rapid commitment of primed cells was inhibited by 12-0-tetradecanoylphorbol-13-acetate and cordycepin but not by cycloheximide. The latter finding indicated that this rapid inducer-dependent commitment event required new RNA synthesis but not new protein synthesis. The precommitment state was lost within six hours of the growth of cells in the absence of inducer but could be sustained longer if cells were incubated in cycloheximide. These studies characterize a precommitment state not previously described and one that appears during chemically induced differentiation in the absence of metabolic inhibitors. The stabilization of these precommitted cells by cycloheximide suggests that the reversibility of precommitment involves new protein synthesis. These findings show that MEL cells proceed to terminal differentiation by accumulating unstable products that must be maintained by the inducer until the final commitment event.

CHEMICAL INDUCTION of erythroid differentiation of murine erythroleukemia (MEL) cells in vitro has facilitated characterization of the commitment process.[1] At a certain point in the differentiation event, MEL cells no longer require the continued presence of the inducer and are termed committed. Analysis of the commitment process, including the use of various inhibitors, has led to the discovery of multiple factors and steps involved in the commitment decision.[2-4]

Recently cell fusion experiments have distinguished between two kinds of inducer-mediated cellular events, one that is MEL cell specific and the other not cell type specific, that act synergistically to produce commitment.[4-6] A protein factor that is not cell type specific and is thought to arise from a disturbance of DNA metabolism has been identified[6] and shown to be active in the differentiation process. MEL cell–specific factors, on the other hand, are less well defined but seem to arise from inducer-mediated transmembrane signals that can be negatively modulated by tumor promoters and have their life span prolonged by cycloheximide treatments.[5] Paradoxically though, the conversion of these signals into factors that are active in reprogramming the developmental fate of MEL cells requires protein synthesis.[5,7,8]

We have been interested in the events that occur during the period preceding terminal commitment.[9] In this communication, we show that suboptimal amounts of inducer will produce cells that although yet uncommitted, are primed for rapid commitment in response to further contact with the same or even a different inducer. This enhanced commitment occurs within three hours of recontact with the inducer, is inhibited by cordycepin and 12-0-decanoylphorbol-13-acetate (TPA) but not by cycloheximide, and is lost within six hours in the absence of inducer. These primed cells represent cells at a reversible intermediate step(s) in the commitment process that have not previously been described.

MATERIALS AND METHODS

Cell cultures. Friend MEL cell lines PC-4, a subclone of the parent line 745 (provided by D. Housman, Massachusetts Institute of Technology), and C7D-Cl, subcloned from cell line C7D,[10] were maintained in culture as described.[9]

Induction studies. Induction was performed on freshly seeded logarithmically growing cells at a density of 10^5 cells/mL in the presence of designated amounts of inducers ie, hexamethylenebisacetamide (HMBA), dimethylsulfoxide (DMSO), or hemin (all obtained from Sigma Chemical Co, St Louis). Cell viability was assessed by trypan blue exclusion. Cell death never exceeded 5% for the first four days of culture. For the induction enhancement studies, cells were grown in inducer at different concentrations for 24 to 72 hours (depending on the experiment) and then either diluted into fresh inducer-containing medium or collected by centrifugation, washed in fresh medium, and resuspended in medium with or without inducer. The number of hemoglobin-producing cells was assayed by the benzidine test[11] 48 hours after replating in fresh medium.

Commitment assays. Commitment to erythroid differentiation was assayed in 1.8% methylcellulose (Fisher Co, Medford, MA) prepared according to Ogawa and Leary[12] and used as outlined by Murate et al.[7] The colonies were examined 72 to 120 hours after plating. The plating efficiency (total colonies greater than single cell/total number of colonies × 100) of uninduced cell lines was always greater than 85%. Colonies were scored for both size (ie, number of cells in each colony) and percentage of cells within each colony that was benzidine-positive (B+). The degree of commitment

was defined, on a percentage basis, as the ratio of B+ colonies (<64 cells in size) to the total number of colonies scored.

In the augmentation experiments, cells previously grown for 48 to 72 hours in an inducer were introduced into similar or different concentrations of fresh inducer. The cells were either collected by centrifugation (500 g for six minutes) and then resuspended into new medium or diluted directly into the new medium; the results were identical. After incubation for various periods of time (three to 24 hours) in fresh inducer, the cells were collected by centrifugation (500 g for six minutes) and resuspended in 0.6 mL of fresh medium from which 0.3 mL was plated into methylcellulose. By this procedure, recovery and cell viability were >95%.

In the inhibition studies, cordycepin (Sigma; final concentration, 20 µg/mL) prepared according to Murate et al,[7] TPA (10 ng/mL; Sigma), and cycloheximide (0.5 µg/mL; Sigma) were added to the cultures at different times in relation to the inducers. In experiments looking at clonal expansion of a subset of cells, the assays were performed in methylcellulose supplemented with different amounts of inducer.

RESULTS

Augmented inducibility of MEL cell lines. Two different MEL cell lines were compared for their response (percent B+ cells) to two inducers, DMSO and HMBA. Both cell lines exhibited similar inducibility with HMBA, but C7D-Cl was more responsive to DMSO (Fig 1).

The induction response was tested when the cells were treated with suboptimal amounts of DMSO (1%) and then replated after 24, 48, or 72 hours into fresh medium and the same amount of inducer. Although replating caused an increased induction at all the times tested, the effect was most dramatic when done at 48 or 72 hours (Fig 2). PC-4 cells left untouched in 1% DMSO contained 15% B+ cells, whereas cultures transferred at 48 or 72 hours into fresh inducer showed 50% to 55% B+ cells when tested at 120 hours.

The same effect was noted when cells were grown in suboptimal levels of HMBA (2 mmol/L) and then replated into fresh medium containing fresh inducer at the same concentration (Table 1). In general the replating produced a greater than twofold increase in B+ cells. This enhanced induction was most marked when low concentrations of inducer were used during the initial contact (Fig 3). When the concentration of HMBA went above 2.5 mmol/L and that of DMSO above 1.5%, the enhancement by replating was dramatically less due to increased induction of the entire cell population. Cells that had not previously grown in inducer remained unaffected by replating into fresh inducer (<1% to 2% B+). When cells grown for 48 hours in inducer-containing medium were collected by centrifugation and resuspended back into the original medium, they showed the same induction level as that of untouched inducer-treated cells.

In these experiments, the cell concentration was reduced three- to fourfold by dilution and replating into fresh medium. In other studies in which the cell concentration was unchanged by the replating procedure, the same increase in

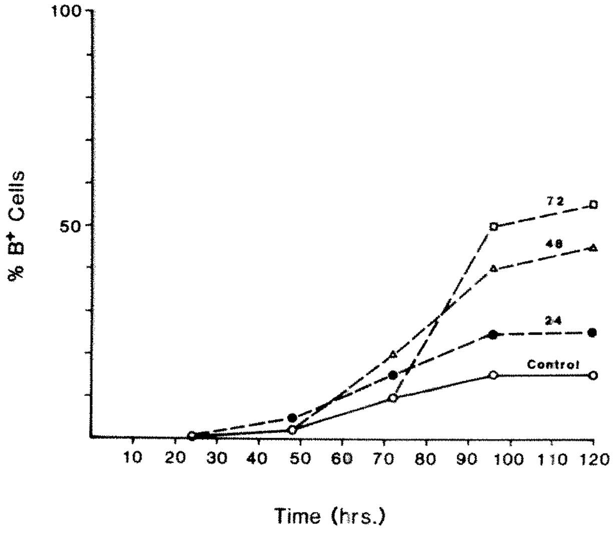

Fig 2. Effect on induction of replating cells suboptimally treated with inducer. PC-4 Cells were incubated in media containing 1% DMSO. One plate (control, solid lines) was kept untouched for the entire test period. At 24, 48, or 72 hours the cells were removed, diluted 1:4 into fresh media with inducer, and placed in separate plates (dashed lines). The percent B+ cells was determined during the entire 120-hour period.

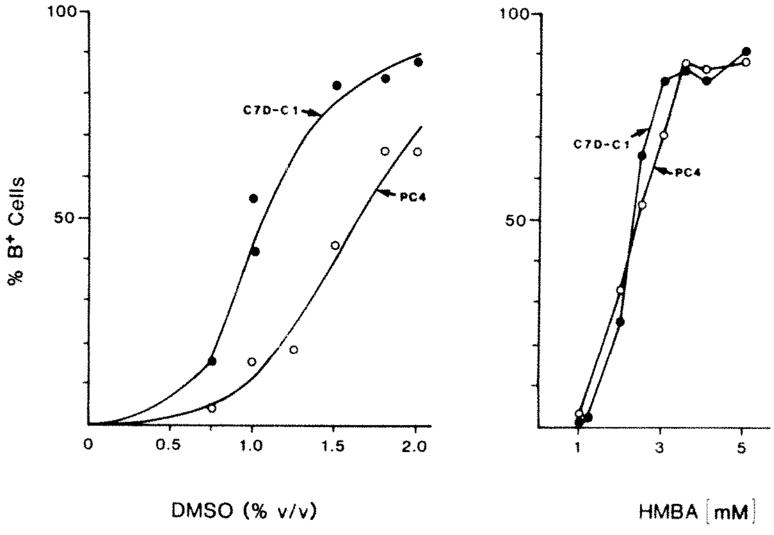

Fig 1. Induction kinetics of C7D-C1 and PC-4 MEL cells in liquid culture with DMSO or HMBA. The percentage of cells that stained with benzidine (% B+) was assayed after 96 hours of treatment. The points represent an average from two to eight separate experiments.

Table 1. Augmentation of Induction of MEL Cell Lines

	Initial Inducer Concentration	Postplating Inducer Concentration	Induction Level of Unreplated Cultures (% B+)	Induction Level of Replated Cultures (% B+)
C7D-C1	1% DMSO	1% DMSO	40.0	60.0
	2 mmol/L HMBA	2 mmol/L HMBA	25.6	63.1
PC-4	1% DMSO	1% DMSO	15.4	37.0
	2 mmol/L HMBA	2 mmol/L HMBA	32.9	71.6

Cells were incubated for 48 hours with suboptimal amounts of inducers and then were replated into fresh media containing the same inducer concentrations. The percent B+ cells was evaluated at 96 hours, 48 hours after replating. These results are representative of many independent experiments.

induction was evident (data not shown). These findings indicated that the augmented induction was not related to a change in cell density.

Augmented induction in replated cultures results from recruitment of inducer primed cells. To determine the basis for the augmented induction upon replating, we replated cells primed for 48 hours with 1% DMSO into 1.8% methylcellulose with or without inducer. At 6, 24, 36, and 48 hours, the plates were scored for growth and benzidine positivity. The augmentation in induction experienced by the primed cells in inducer-treated liquid cultures was faithfully reproduced in inducer-containing methylcellulose (Fig 4A). Furthermore, because there was an increase of B+ colonies (Fig 4B), the replating procedure caused a significant recruitment of primed cells for differentiation along the erythroid pathway. This recruitment does not take place in the absence of inducer (control, Fig 4) or with unprimed cells (data not shown).

In these experiments, the dual scoring of colony for both size and benzidine phenotype allowed a clonal comparison of growth rates. Over the initial 24- to 36-hour period, DMSO-treated cells did not show any difference in growth kinetics from that of control cells in methylcellulose containing or not containing inducer. Later, however, it became apparent that regardless of the growth rates of the cultures as a whole, a substantial portion of the B+ colonies grew slower than the benzidine-negative ones. These findings provide further evidence that the rapid augmentation in induction in replated cultures is not due to a clonal expansion of already induced cells but is due to a fresh inducer-specific mediated event(s) on primed cells.

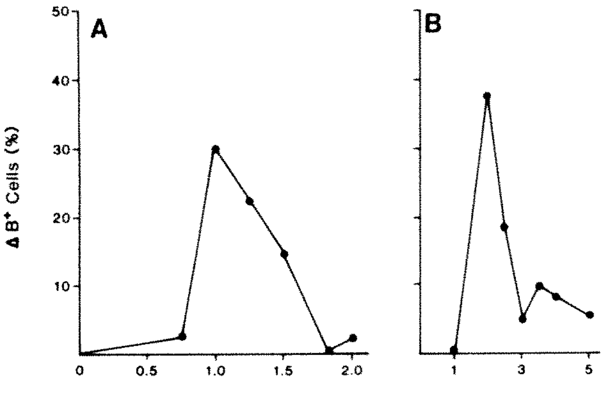

Fig 3. Effect of inducer concentration on augmentation of induction. MEL cells were grown for 48 hours at varying concentrations of inducer and then replated in fresh medium and inducer at concentrations identical to that in the initial growth period. The percent B+ cells was assessed 48 hours after replating. The difference (Δ) in percent B+ cells present in the replated culture as compared with those left in the initial inducer medium is plotted against the inducer concentration.

HMBA and DMSO, but not hemin, can be interchanged without loss of augmentation of induction. To establish whether the augmented induction was inducer specific or could be effected by ones other than those used initially (ie, in the priming period), we replated 48-hour cultures primed either with 1% DMSO or 2 mmol/L HMBA in fresh medium containing 100 µmol/L hemin or varying concentrations of DMSO or HMBA. Exchanging DMSO or HMBA in the postpriming period gave the same augmented induction relative to using the same inducer in the priming and postpriming periods. No additional augmentation was found by increasing the concentration of the inducer in the postpriming period (Table 2). No augmentation was found when primed cells were incubated with hemin (100 µmol/L) (Table 2). These findings showed that the primed state was responsive to more than a single inducer but did appear to distinguish between those inducers that lead to commitment (DMSO, HMBA) and hemin, which does not.[13]

Augmented induction in replated cultures reflects an augmentation in commitment. To determine whether the augmented induction of B+ cells was related to terminal differentiation, we examined the production of B+ colonies in methylcellulose from 48-hour DMSO-primed cultures after replating for various times (12 to 24 hours) in fresh medium and 1% DMSO. After growth for 96 hours in methylcellulose, colonies that displayed benzidine positivity and contained less than 64 cells in size were considered terminally committed.[7] We noted that replating DMSO-primed cultures at 48 hours always led to an increase in number of committed cells (Table 3). In the absence of inducer (ie, when primed cells were replated in fresh medium alone) there was little change in commitment relative to cultures that were not replated.

To define the minimum time needed for the augmentation, we examined the effect of short periods of contact with fresh inducer after the 48-hour priming period. Replated cultures required only three to six hours of additional contact with inducer to achieve augmentation in commitment (Fig 5). This augmentation was maximal by 12 hours with no further change with 24 hours of additional contact with suboptimal amounts of inducer (Fig 5, Table 3).

The lower level of commitment in cultures not replated

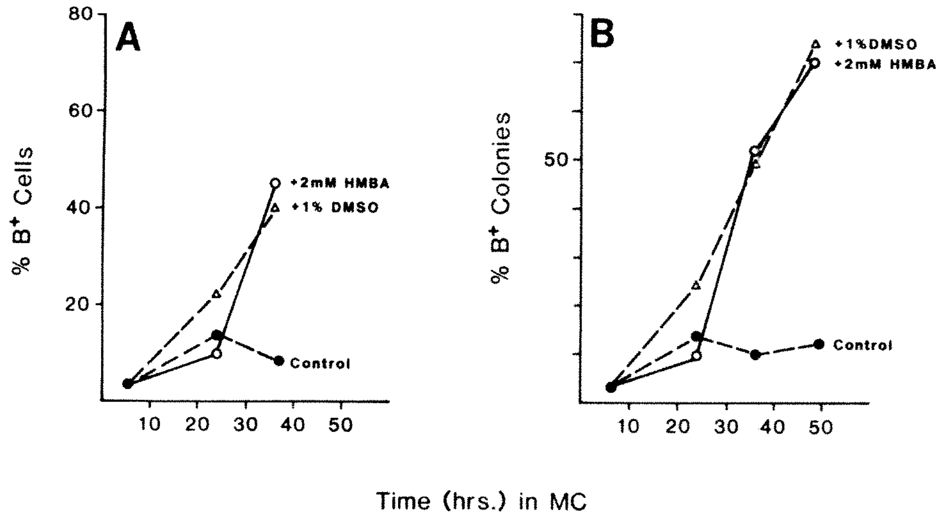

Fig 4. Augmentation in induction of primed cultures upon replating into inducer-containing methylcellulose. One percent DMSO-treated PC-4 cells from 48-hour-old cultures were imbedded in 1.8% methylcellulose at approximately 10^6 cells/mL. The methylcellulose contained either no inducer (control), DMSO (1%), or HMBA (2 mmol/L). The plates were benzidine stained at 6, 24, 36, and 48 hours of growth in methylcellulose. At these times the plates were scored for both the percent B+ cells (A) among the total cells in at least 300 colonies and the percent B+ colonies (B).

could relate to depletion of factors present in the medium needed for terminal differentiation. This possibility was tested by substituting the fresh inducer in a fresh medium combination with (*a*) fresh inducer in medium aged at 37°C for 60 hours (*b*) fresh inducer in 0.2-μm–filtered spent medium taken after 60 hours from untreated cell cultures, or (*c*) medium and DMSO incubated for 60 hours without cells and without the addition of fresh inducer. None of these substituted media altered the level of augmented commitment (data not shown). The findings suggest that it is the inducer not the media that needs to be fresh to drive primed cells into a committed state. They also suggest that DMSO is altered or depleted in media containing cells but remains unchanged if incubated alone in medium.

The level of enhanced commitment is related to the concentration of inducers in priming but not the postpriming period. The increase in newly committed cells was greater when MEL cells were primed with low (suboptimal) amounts of inducer when presumably a greater proportion of precommitted cells were present (Fig 6). At 1% DMSO an additional 20% B+ colonies were seen in PC-4–plated cells.

Table 2. Effect of Exchange of Inducers in Postpriming Period on Induction of PC-4 Cells

Priming Condition	Postpriming Condition	Induction Level of PC-4 Cells (% B+ Cells)
2 mmol/L HMBA	Fresh medium	29.3
	Untouched	32.9
	2 mmol/L HMBA	54.5
	1% DMSO	57.3
	1.25% DMSO	56.0
	1.5% DMSO	60.0
	100 μmol/L hemin	27.0
1% DMSO	Fresh medium	11.5
	Untouched	15.4
	1%	37.0
	1.25%	40.0
	2 mmol/L HMBA	35.0
	5 mmol/L HMBA	25.0
	100 μmol/L hemin	18.0

Priming and postpriming periods were 48 hours each. Results presented are representative of several independent experiments.

This number of newly committed cells remained present despite an increased total commitment of the population up to 1.8% DMSO. At 2% DMSO the replating did little to augment commitment when the culture was over 80% committed. Increasing the postpriming concentration of inducer over that used during priming did not lead to further augmentation (data not shown).

Proliferative potential of primed cells. We compared the colony size distribution of cells from primed cultures resuspended for six hours in fresh medium without or with fresh inducer. The newly committed cells that resulted from the fresh inducer contact gave rise to B+ colonies that were composed of two to 64 cells. As compared with control cells, cells incubated with fresh inducer for this short period did not show a change in benzidine-negative colonies in this size range. These findings indicate that the newly committed cells do not arise from a more efficient inducer-driven hemoglobinization of already terminally committed cells.

TPA and cordycepin but not cycloheximide, if present in the postpriming period, will inhibit the augmented commitment. To gain an insight into the biochemical processes that force replated primed cells into a state of commitment, we incubated 1% DMSO-primed cultures for six hours in fresh medium containing either 1% DMSO or 2 mmol/L HMBA and either 10 ng/mL TPA, 20 μg/mL cordycepin, or 0.5 μg/mL cycloheximide before plating in methylcellulose. Irrespective of the inducer used in the postpriming period, TPA and cordycepin completely eliminated the augmentation of commitment (Fig 7). In contrast, cycloheximide had

Table 3. Augmentation of Commitment of PC-4 Cells Primed for 48 Hours With 1% DMSO

Additional Time in Original Medium or in Fresh Inducer (h)	Percent Commitment*		
	Original Medium	Fresh Medium + 1% DMSO	Difference
0	26	—	—
12	24	50.5	26
18	21	51	30
24	21.3	44.9	23

*Percentage of B+ colonies assayed after 96 hours in methylcellulose. The results are representative of several independent experiments.

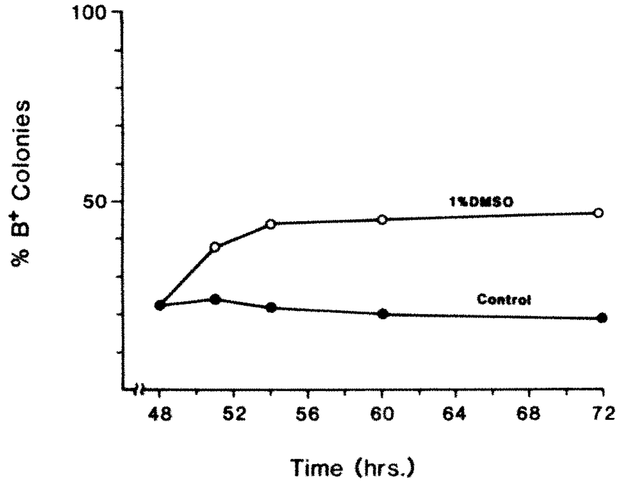

Fig 5. Kinetics of augmented commitment upon replating. PC-4 cells primed for 48 hours with 1% DMSO were resuspended in fresh media with 1% DMSO for 3, 6, 12, or 24 hours before embedding in methylcellulose. The percent B+ colonies were assayed after 96 hours.

no effect on the augmentation; at this concentration, cycloheximide completely inhibited cell growth (data not shown). These latter findings suggest that during the postpriming period the rapid inducer-mediated augmented commitment required RNA but not new protein synthesis. Furthermore, the findings indicate that either the synthesis of the RNA or its eventual translation or degradation is modulated by a TPA-sensitive step(s).

Stability of primed state; effect of cycloheximide. We examined the stability of the primed state of PC-4 cells treated for 48 hours with 2 mmol/L HMBA. If the cells remained in the priming medium, as shown previously (Fig 2), they retained the ability to become rapidly committed with fresh inducer during the 12-hour test period (Fig 8A). Upon transfer to fresh medium without inducer, the primed cells lost their ability to respond to fresh inducer within 12 hours (Fig 8B). This rather rapid loss (ie, half-life of approximately six hours) was partially prevented by the addition of cycloheximide (0.5 μg/mL) to the fresh medium (Fig 8C).

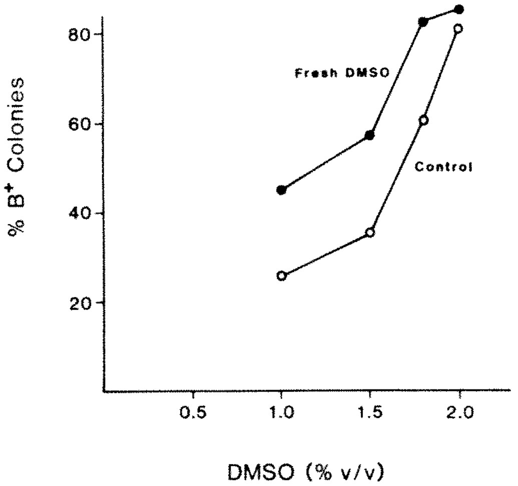

Fig 6. Effect of initial inducer concentration on number of primed cells. PC-4 cells were primed for 72 hours with varying amounts of DMSO and then replated in fresh medium with the same amount of fresh inducer for 12 hours or left untouched for an additional 12 hours (control). The percent B+ colonies in the cultures was assessed after 96 hours of growth in methylcellulose.

DISCUSSION

Intrinsic in the hypothesis that inducer-mediated commitment is a multistep process[2,3] is the idea that there are in inducer-treated MEL cell cultures cells that have experienced several biochemical events of the differentiation process, are not fully committed, but have the ability to become so if appropriately stimulated. These cells, which can be defined as precommitted or primed for commitment, may exist in several states depending on the number of events in the commitment process that they have completed. Examples of MEL cells that are progressively closer to terminal commitment are those that retain a memory of a prior exposure to inducer[14] and those that will commit rapidly in the presence of inducer after the removal of inhibitors of commitment: cordycepin,[15] amiloride,[16] or dexamethasone.[7] There are also those cells that no longer require inducer to complete commitment but can be kept from doing so by TPA.[17] Primed cells have also been described in cultures of human myeloid leukemia cells that after contact with one inducer, retinoic acid, responded to the differentiation effects of another.[18]

We have enriched MEL cell cultures for precommitted cells by their growth in suboptimal amounts of inducers. This method does not require treatment of cells with inhibitors of the commitment process, cell fusions, or extensive subcloning for particularly responsive cell populations.[7] However, these cells, like MEL cells released from the block by various inhibitors, also require brief additional fresh inducer contact to complete the commitment process. The ease with which these cells are obtained make them a useful tool in the analysis of the rapid inducer-driven molecular events that operate in the later stages of the commitment process. We found that these precommitted cells both differed from and resembled commitment-inhibited cells and MEL cell fusions. They are different from dexamethasone-treated cells in that their augmented commitment was inhibited by cordycepin but not cycloheximide[7] (Fig 7). These cells are thus at a step in the terminal commitment process that does not require the immediate synthesis of new proteins but, presumably, the synthesis of a relatively stable poly-A–containing RNA molecule. In this way they resemble cells blocked in commitment by cordycepin,[15] although it is unclear whether they are biochemically identical; comparable inhibitor studies were not performed on cordycepin-treated cultures. Moreover, our studies showed that the commitment-related RNA remains stable or is continuously made while untranslated during six hours of cycloheximide treatment or as long as inducer is present. Our experiments also indicate that a TPA-sensitive step may either precede the inducer-driven RNA synthesis or be involved in metabolizing the newly induced RNA(s) or in producing the target(s) to which the product of this RNA(s)

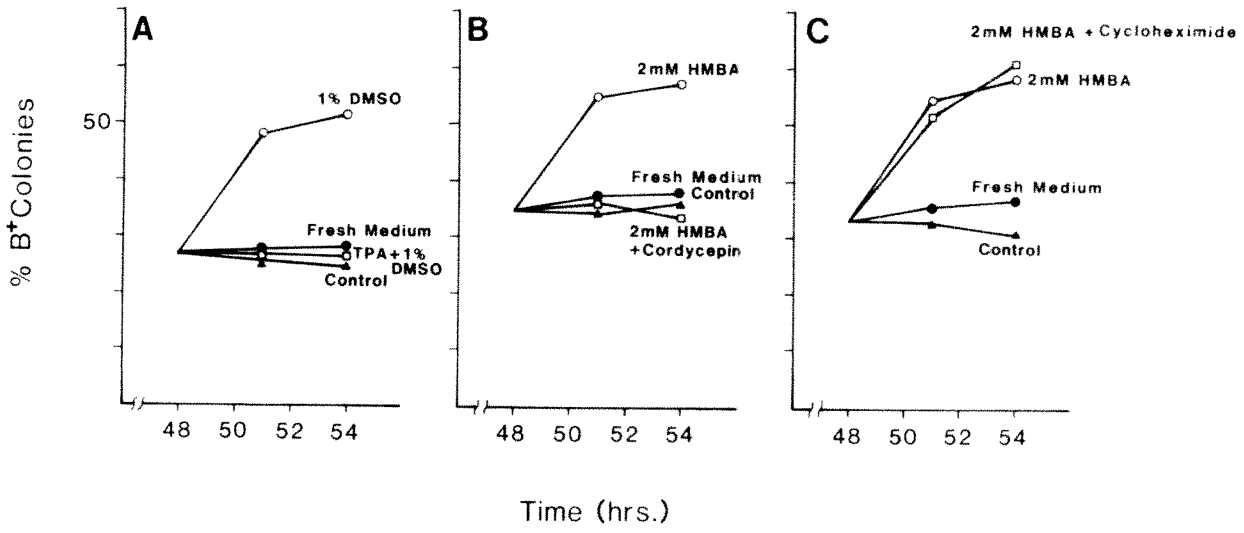

Fig 7. Effect of TPA, cordycepin, or cycloheximide on augmentation of commitment. PC-4 cells were primed for 48 hours in 1.0% DMSO (A) or in 2 mmol/L HMBA (B, C). The cells were then either left untouched (control) or collected and incubated in fresh medium or medium with fresh inducer with or without different inhibitors. (A) Fresh medium with fresh 1% DMSO ± 10 ng/mL TPA. (B) Fresh medium with fresh HMBA with or without cordycepin (20 μg/mL). (C) Fresh medium with fresh HMBA ± 0.5 μg/mL cycloheximide. At three and six hours after incubation, the cells were collected and imbedded in methylcellulose (1.8%) at a concentration of 10^6 cells/mL. The level of commitment (ie, percent B+ colonies) was evaluated after 120 hours of growth in methylcellulose.

is directed. This effect of TPA is distinct from what inhibits final commitment[17] because the removal of TPA did not cause primed cells to become committed. The primed cells, therefore, also provide a potential system for studying the events that precede this inducer-independent (TPA-sensitive) commitment step. On the basis of its rapidity of onset, this inducer-dependent event is akin to the rapid inducer-mediated TPA-inhibitory step demonstrated in the MEL cell fusion partner.[6]

Primed cells also resemble the MEL cell fusion partner[5] as well as dexamethasone-blocked cells[7] in being unstable once inducer contact is terminated (Fig 8). However, we showed that the primed state could be stabilized by inhibiting protein synthesis with cycloheximide, which is reminiscent of the

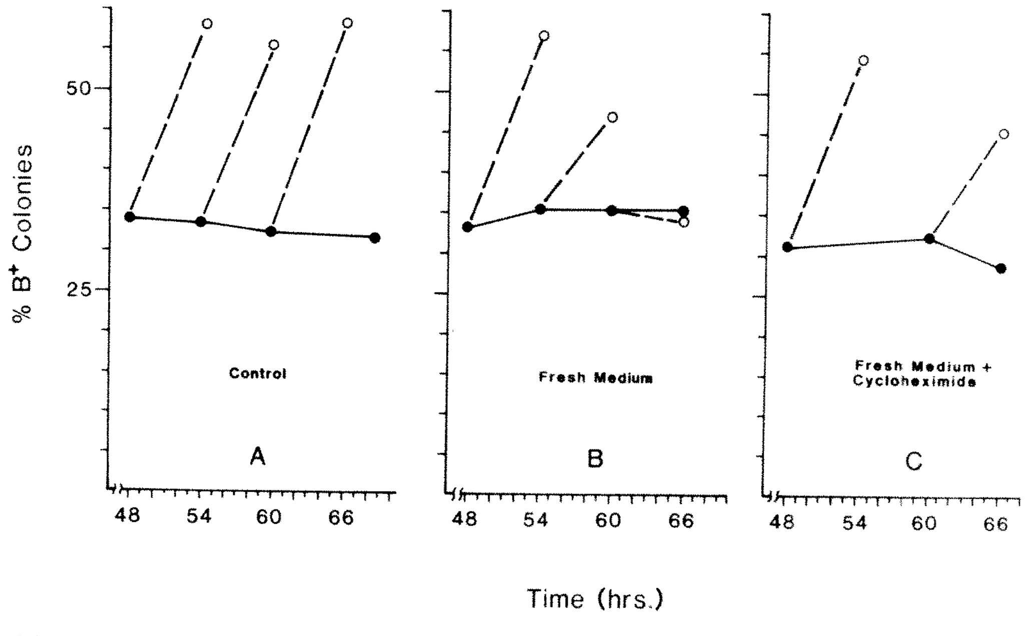

Fig 8. Stability of primed cells and effect of cycloheximide. PC-4 cells primed for 48 hours with 2 mmol/L HMBA were collected by centrifugation and immediately resuspended either in (A) their own medium, (B) fresh medium, or (C) fresh medium with cycloheximide (0.5 μg/mL). At 0, 6, and 12 hours after replating, a portion of the cells were recentrifuged and rechallenged with fresh medium containing 2 mmol/L HMBA for six additional hours. At the end of this period, the cells were imbedded in methylcellulose and the percent B+ colonies recorded after 110 hours. Key ●—●—, level of commitment in control cultures not replated in fresh inducer; O--O, level of commitment in cultures that were incubated in fresh medium and 2 mmol/L HMBA.

effect of cycloheximide on the postulated inducer-dependent transmembrane activity in cell fusion experiments.[6] This finding implicates a protein product in reversing the precommitment state.

The evaluation of the commitment assays in terms of both colony size and benzidine phenotype allowed us to better define several characteristics of the primed cells. First, these cells do not seem to derive exclusively from cells that in the primed cultures give rise only to sectored colonies (ie, mixed benzidine phenotype colonies). The proportion of mixed colonies remained low (ie, <5% of the total colonies) whether the primed cultures were left undisturbed or briefly recontacted with fresh medium with or without inducer or metabolic inhibitors. Second, primed cells are not all at the same physiological state; commitment takes place in cells that can undergo from one to six cell divisions. Third, it is unlikely that brief inducer recontact only leads to increased hemoglobinization of already committed cells because in the undisturbed, replated, or metabolic-inhibited primed cultures we never found a significant portion of cells that underwent a limited proliferation without expressing the B+ phenotype. Moreover, hemin, which induces hemoglobin synthesis,[13] did not increase commitment (Table 2).

The dependence of primed cells on fresh inducer, and not fresh medium to complete the commitment, suggests that the inducer (DMSO or HMBA) is altered or depleted after 24 to 48 hours in the presence of MEL cells. Previous studies with radiolabeled DMSO showed accumulation of the label in MEL cells.[19] With higher (optimal inducing) concentrations of inducer, enough active inducer must still be present throughout the three-day period needed to complete the inducer-mediated events. The fact that spent inducer maintains the primed state (Fig 8A) suggests that even if some of the inducer is altered or depleted sufficient amounts are present to maintain cells in a primed state.

Although the events leading to commitment appear to be sequential, these data together with those presented by others[3,6,7,14,15] suggest that the different components of the terminal commitment event do not need to be synchronously made to be effective. Nor do their activities appear to be limited to a particular step in the commitment process, but instead they seem required and must be inducer maintained throughout a precommitment period. Commitment, therefore, emerges from an accumulation of these factors, independently synthesized but interdependent, all of which remain inducer driven and required until the final commitment event.

Mechanism of Erythrocyte Aggregation and Sedimentation

By Thomas L. Fabry

Unstirred suspensions of erythrocytes form stable spherical aggregates of uniform size. The radius of the spheres depends upon the suspending medium and the hematocrit. Erythrocyte suspensions will undergo sedimentation only after these aggregates are formed. Aggregation is a two-step process: first, erythrocytes associate in long chains (rouleau formation). Next, these chains form spheres of uniform size. The requirements for this well-defined process are an electrolyte and a neutral or negatively charged macromolecule in the solution and a metabolically active red cell. If these conditions are not met, red cells either will not aggregate at all or will form amorphous aggregates. Rouleau formation and sedimentation are inhibited by 4,4′-diisothiocyanatostilbene-2,2′-disulfonic acid, an inhibitor of anion transport, but not by ouabain, a cation transport inhibitor. The kinetics of erythrocyte sedimentation reflects the aforementioned mechanism: no sedimentation occurs during rouleau formation. Once the spheres of uniform size are formed, they will settle according to the Einstein-Stokes equation. In this model, parameters of sedimentation kinetics are the delay before sedimentation starts, the rate of sedimentation in the steady state, and the radius of the sedimenting aggregate. The radius can be calculated from the rate of fall of the aggregates and agrees well with the microscopically observed radius. It is inversely proportional to the hematocrit, which explains the elevated sedimentation rates in anemia.

THE ERYTHROCYTE SEDIMENTATION RATE (ESR) is a useful qualitative empirical index of nonspecific disease activity.[1] Its clinical usefulness is, however, limited by three major problems: (*a*) quantitative interpretation is not possible, (*b*) there is a poor correlation with measurements of other acute phase reactants, and (*c*) it is paradoxically low in several diseases (eg, certain forms of inflammatory bowel disease,[2] sickle cell disease,[3] and possibly in congestive heart failure[4]). Increased ESR has been attributed to increased amounts of some plasma proteins (fibrinogen,[5] etc), but again there is only very poor quantitative correlation. Expressing the sedimentation rate as the amount of sedimentation at one hour is only meaningful if the process occurs uniformly over time. Any deviation from zero-order kinetics means that more than one parameter must be used to describe the process.

Chien[6] laid the foundation for interpreting the rheology of red cell suspensions. He established the need for electrolytes and macromolecules to be present in the suspending medium for rouleau formation to occur. Perelson and Wiegel,[7] using techniques of statistical mechanics, showed that the average rouleau size increases as the adhesion energy between erythrocytes increases. Samsel and Perelson[8] developed an elegant kinetic model for rouleau formation and pointed out that as rouleaux grow large they form rings and branching aggregates. Evans and Buxbaum[9] and Buxbaum et al[10] quantified the surface affinities of erythrocyte membranes for macromolecules and related them to aggregation.

Quantitative interpretation of the sedimentation rate is possible by developing a kinetic model based on the underlying mechanism. This may make erythrocyte sedimentation a useful tool for investigating the pathophysiology of some diseases. Furthermore, quantitative interpretation of sedimentation may provide an inexpensive screening test of plasma protein and erythrocyte membrane abnormalities in some less common disorders.

MATERIALS AND METHODS

Blood specimens anticoagulated with K_3EDTA were obtained from healthy volunteers and were processed immediately after collection. Red cells were suspended in autologous plasma to obtain different final hematocrit values (Hct). For the inhibition experiments, washed red cells were incubated with 4,4′-diisothiocyanatostilbene-2,2′-disulfonic acid (DIDS) (0.1 mg/mL) for 30 minutes at 37°C. This is the same concentration of DIDS that is used to inhibit the chloride/bicarbonate antiporter of the erythrocyte membrane. After incubation the cells were washed with isotonic saline containing 10 mmol/L glucose and then reconstituted with plasma.

Ouabain (Sigma Chemical Co, St Louis) was dissolved in water (0.01 mol/L stock solution; final concentration of incubation mixtures, 0.1 mmol/L). DIDS was prepared in HEPES buffer immediately before use. Other chemicals were obtained from standard sources.

Sedimentation experiments were performed in Kimble disposable 200-mm Westergren tubes at pH 7.4 and at 25 ± 2°C. Experiments were completed within three hours of sample preparation to avoid artifacts from irreversible aggregation of red cells. To obtain the photomicrographs, erythrocyte suspensions were allowed to sediment in rectangular cross-section tubes 0.2 × 5 or 0.3 × 5 mm and 100 mm long (Vitro Dynamics, Rockaway, NJ). The kinetics of sedimentation in this tube is the same as in a Westergren tube filled to 100 mm. The tubes were placed flat side down on the microscope stage in different phases of the sedimentation, and photographs were taken at 4× and 10× magnification.

Curve fitting and statistical calculations were carried out by using the computer programs SAS[11] and Statgraphics.[12] The Einstein-Stokes equation was used as derived by Hiemenz.[13]

RESULTS

Kinetics of erythrocyte sedimentation and the effect of Hct. Erythrocyte sedimentation follows an S-shaped curve with time (Fig 1 and Table 1). There is a delay in the start of sedimentation; during this time the rate of sedimentation is

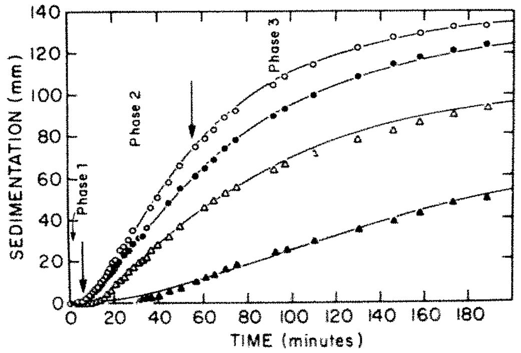

Fig 1. Sedimentation as a function of time at different Hct values. ○, Hct of 26; ●, Hct of 28; △, Hct of 34; ▲, Hct of 45.

zero (phase 1 of the curve). The next segment (phase 2) is linear: sedimentation continues at a constant rate. Finally, in phase 3 the rate levels off to zero: sedimentation is completed.

At different red cell concentrations (Hct range, 10 to 50) the shape of the curve is qualitatively the same; however, there is a shift to the right as the Hct increases (Fig 1): the delay (phase 1) increases and the slope in phase 2 decreases. This results in slower sedimentation at a higher Hct value.

Effect of membrane transport inhibitors on sedimentation. DIDS, an irreversible inhibitor of anion transport, inhibits both rouleau formation and sedimentation in a dose-dependent manner. Ouabain (0.1 mmol/L) has no effect on the sedimentation rate. Table 2 shows the slope of the sedimentation curve and the ESR as a function of inhibitor concentration.

Direct observation of aggregation during sedimentation. In phase 1 the homogeneous red cell suspension forms a three-dimensional network (Fig 2) that, late in this phase, rearranges to form spheres of equal size. This is a sudden change. It can be observed with the naked eye in the Westergren sedimentation tube: the homogeneous cell suspension suddenly becomes granular in appearance, with the spheres visible at the sides of the tube. In phase 2 these spheres sediment at a steady rate (Fig 3). Figure 4 is a photomicrograph of the interface between the sedimented cells and the plasma. The sedimenting entities are the spheres formed from the rouleaux. The extent of aggregation does not change during phase 2. To demonstrate that the red cells form fairly stable aggregates during the steady phase of sedimentation (ie, after the delay period) the ESR tube was gently inverted (ie, turned upside down). Sedimentation continued at the same steady rate without a second delay period.

Table 2. Effect of Anion and Cation Transport Inhibitors on Sedimentation

Inhibitor	Concentration (μmol/L)	Slope	ESR
Blank		0.6	28
DIDS	1	0.5	23
DIDS	10	0.1	5
Oubain	100	0.6	23

DISCUSSION

The delay in red cell suspension sedimentation suggests either aggregation (ie, red cells will not settle until aggregates of sufficient size are formed) or cooperatively (ie, the rate constant for the sedimentation increases with time). Red cell sedimentation kinetics is not compatible with either. Simple aggregation would require the sedimentation rate to increase with an increasing concentration of erythrocytes (Hct); in fact, the opposite occurs. As shown in the Appendix, the equation describing sedimentation kinetics does not fulfill the criteria for cooperativity.

Aggregation of red cells to form uniform spheres. The mechanism of rouleau formation has been extensively investigated.[14] Our data allow further elaboration of the mechanism of aggregation.

Red cells repel each other because of their negative surface charge from sialic acid residues. At the same time they are attracted by the van der Waals forces, which are electrodynamic in nature. The balance of these two forces determines the most stable arrangement of red cells in an electrolyte solution in the absence of other forces. Assuming a discoid shape for red cells, van Oss and Absolom[15] calculated that at an intercellular distance of 103 nm there is a minimum of -4.6×10^{-12} ergs/cell in the potential energy distribution of erythrocytes suspended in isotonic saline. The distance of the closest approach for erythrocytes increases with decreasing electrolyte concentration because the repulsive force (ζ potential) increases with decreasing ionic strength and the van der Waals forces are unchanged. (This explains why there is no rouleau formation in the absence of electrolytes, eg, in sucrose solutions.) Therefore, in the presence of electrolytes, the most stable configuration of erythrocyte suspensions is a chain of cells attached by their flat surfaces. However, this energy is small relative to the energy from Brownian motion (kT); therefore, cells would align only transiently but would not form stable structures. For this reason red cells will not form rouleaux if the suspending solution contains electrolytes only.

For rouleau formation to occur, macromolecules must be present in the suspending medium.[16] Chien and Jan[17] showed

Table 1. Measured and Derived Parameters Describing the Curves in Fig 1

Hct	a_0	a_1	a_2	Slope (100 × mm/s)	Delay (min)
25.8	152 ± 2	2,645 ± 56	11 ± 2	2.4	6.5
28.6	152 ± 2	3,081 ± 82	29 ± 3	2.1	8.0
35.8	123 ± 4	4,629 ± 239	31 ± 9	1.6	13.0
44.7	80 ± 10	26,324 ± 1,545	−38 ± 35	0.5	30.0

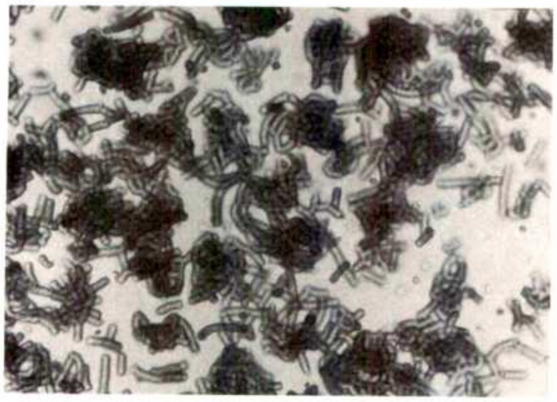

Fig 2. Photomicrograph (original magnification ×40; current magnification ×16) of sedimenting erythrocytes in a 0.2-mm-diameter tube. The rouleaux are starting to form spheres: phase 1 of Fig 1.

that increasing the length of a macromolecule (dextran) will increase the intercellular spacing of the red cells in the rouleau. He concluded that the macromolecule actually bridges two erythrocytes and only elongated macromolecules of sufficient length can serve this function. For example, fibrinogen but not albumin meets the shape requirements to cross-link erythrocytes. Therefore, sedimentation will not take place in serum. It has not been made clear until now, however, that the macromolecule has to be either neutral or negatively charged (as opposed to positively charged).

The receptor (binding) site for the macromolecule on the erythrocyte membrane has not been identified. We have shown that DIDS, an inhibitor of anion transport, interferes with formation of the aggregates in either plasma or dextran. DIDS at similar concentrations inhibits the chloride-bicarbonate exchange across the red cell membrane.[18] This suggests that the macromolecule binds at the anion transport site. DIDS also reacts with lysine residues on the membrane surface. If the fibrinogen binding involves these lysine residues, then DIDS would interfere at this point. Against this latter possibility is the fact that there are 10^6 anion transport sites (band 3 protein)[19] per erythrocyte and about 10^4 fibrinogen molecules are bound to each cell at equilibrium.[20] Because fibrinogen binding is weak, the 100:1 ratio of binding sites to bound molecules is the right order of magnitude. In the case of rouleau formation, the two ends of the macromolecule bind to adjoining erythrocytes to form the aggregates.

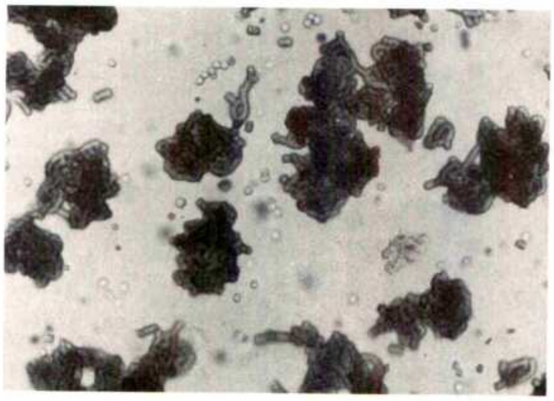

Fig 3. Photomicrograph (original magnification ×40; current magnification ×16) of sedimenting erythrocytes in a 0.2-mm-diameter tube: phase 2 of Fig 1. Note the uniform size of the spheres.

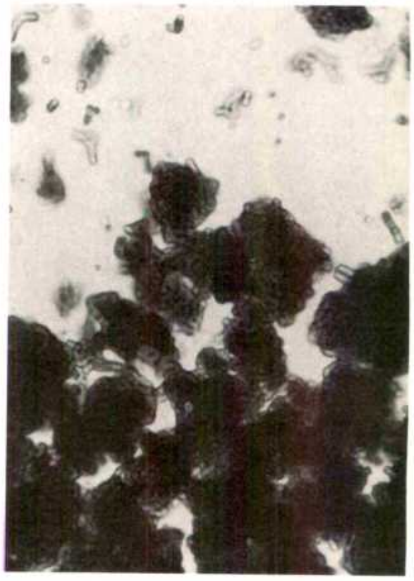

Fig 4. Photomicrograph (original magnification ×40; current magnification ×16) of sedimenting erythrocytes in a 0.2-mm-diameter tube at the interface between the clear plasma and the sedimented red cells: phase 3 of Fig 1. Note that the sedimenting entities are spheres formed from rouleaux and not individual red cells.

In contrast to the aforementioned mechanism, positively charged macromolecules are not able to bridge the erythrocytes in this fashion; they react with the sialic acid residues and form amorphous aggregates.[21] This process is not inhibited by DIDS.

After the formation of the rouleaux, the chains form spheres of uniform size (Fig 3). The driving force may be the reduction of the surface free energy. Uniform size is probably the result of competition between the attractive forces between cells and the hydrodynamic forces that tend to reduce the size of the spheres.

The spheres contain not only erythrocytes but also the macromolecules binding them together. This is in agreement with the findings of Janzen et al[22] who demonstrated binding of fibrinogen to red cell surfaces. It also explains why increased Hct values do not increase the rate of sedimentation: the formation of the spherical aggregates is limited by the availability of fibrinogen or other plasma macromolecules linking the erythrocytes.

In summary, the mechanism of red cell aggregation to spheres of uniform size proceeds via the following steps: (*a*) electrostatic forces draw erythrocytes together to about 100 nm, with the discoid shapes lining up parallel to one another. This requires the presence of electrolytes. (*b*) If a neutral or negatively charged macromolecule of length greater than

100 nm is present, it will bind to the anion transport sites of adjoining erythrocytes. The energy of this binding will stabilize the parallel configuration of red cells, and rouleaux are formed. (*c*) Rouleaux rearrange to form spheres, which reduces the surface free energy. (*d*) The kinetics of sedimentation must be described by at least two independent parameters (eg, delay before sedimentation starts and steady-state rate of sedimentation). For a mathematical analysis see the Appendix.

Clinical correlation: correction for Hct. In clinical practice there are two reasons for variations in the sedimentation rate: (*a*) its dependence on Hct and (*b*) its dependence on the plasma protein concentration. The latter makes it useful as an empirical index of disease activity. In Fig 5 the radius of the sedimenting sphere (which is directly proportional to the true rate of sedimentation) is shown as a function of Hct and plasma protein concentration. The radius is increased by either decreasing the Hct or increasing the plasma protein concentration. Therefore, a change in Hct masks the effect of changing plasma protein concentration and composition. Because the steady-state sedimentation (slope in phase 2) in the range of Hct 10 to 50 is a linear function of Hct (Fig 6), correction can be made by interpolating to a set value, eg, to an Hct of 40. This eliminates the variations in the sedimentation rate due to the changes in Hct. In practice a good estimation of the steady-state sedimentation can be obtained by measuring the amount of sedimentation at 30 and 60 minutes and multiplying their difference by 2 (this way the sedimentation will have a value that is similar to the ESR). Because the value of the slope approximates 0 when Hct = 55, one can obtain the value at an Hct of 40 from the value measured at any other Hct by the relationship: Sed (Hct = 40) = Sed (observed) × (55 − 40)/(55 − Hct), (equation 1), where Sed (observed) is the sedimentation observed at the given Hct and Sed (Hct = 40) is its value corrected to Hct 40.

Table 3 shows both Sed (observed) and ESR and their values corrected to Hct 40 by using equation 1. In a larger series of patients with inflammatory bowel disease we obtained identical results. Clearly Sed (Hct = 40) provides an index of disease activity that is fairly independent of Hct.

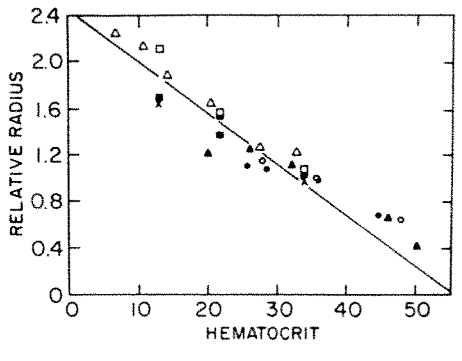

Fig 5. Radius of the spherical aggregates at different Hct values. Erythrocytes are suspended in autologous plasma and serum mixtures. The third coordinate is the fraction of plasma in the suspending medium.

Table 3. Hct Correction of Sedimentation by Using Equation 1

Hct	Sed (observed)	ESR	Sed (Hct = 40)	ESR (Hct = 40)
25.8	80	80	41	41
28.6	70	65	40	37
35.8	46	42	38	33
44.7	22	11	36	18

Sed (observed) and ESR are experimentally determined (see the text). Sed (hct = 40) and ESR (Hct = 40) are the calculated corrected values.

APPENDIX

By using SAS for modeling, the best functional form of the kinetics of erythrocyte sedimentation is as follows: sedimentation = $a_0 \times t^2/(a_1 + a_2 \times t + t^2)$ (equation 2), where t is the sedimentation time and the a's are experimental parameters. For a cooperative phenomenon $a_2 = 0$.

Two additional descriptive parameters can be derived from the three parameters in equation 1. The first is the delay before sedimentation starts, ie, the length of phase 1. The second is the slope of the linear part of phase 2. These two entities are related to the parameters in equation 2: the slope is the value of the first derivative of equation 2 when the second derivative is equal to zero and the delay is the x-intercept of the straight line originating from the inflection point of this curve and having the calculated slope. Alternatively, these can be directly measured from the plot of the curves in Fig 1. Table 1 gives the values for these parameters for the curves from Fig 1.

The linear part (phase 2) of the sedimentation results as the spheres formed from the rouleaux fall in a viscous medium. The radius R of this sphere can be calculated from the Einstein-Stokes equation: $R^2 = 9\, v\, \eta/2(\sigma_2 - \sigma_1)g$ (equation 3), where η is the plasma viscosity, σ_1 is the plasma density, and σ_2 is the red cell density. The densities and viscosities are literature[23] values, and v is the measured rate of sedimentation in the linear phase (phase 2).

These radii can also be measured in the photomicrographs. Figure 6 shows both the calculated and measured values for the radii as a function of Hct for seven samples for a series of different Hct values. Because the concentration of the bridging macromolecules was different in each series, the radius is expressed relative to that at Hct 35. There is an excellent agreement between calculated and measured values.

ACKNOWLEDGMENT

Valuable discussions with Drs Jean-Claude Justice and Marie-Claude Justice and the assistance of Dr Steven Dikman with the photomicrographs are gratefully acknowledged. I am very grateful to Karen Sadock for her editorial review.

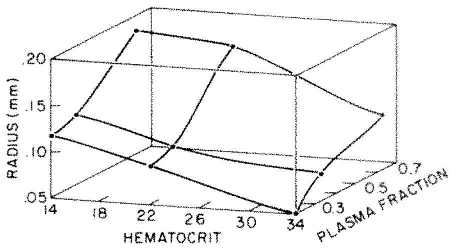

Fig 6. Radius of spherical aggregates as a function of Hct. The seven different symbols represent different blood samples. The radius is expressed relative to that observed at Hct 35.

Localization of a Collagen-Interactive Domain of Human von Willebrand Factor Between Amino Acid Residues Gly 911 and Glu 1,365

By Michel Kalafatis, Yukihiro Takahashi, Jean-Pierre Girma, and Dominique Meyer

A collagen-binding domain of von Willebrand factor (vWF) has been identified in the central part of the molecule by comparing the binding properties of vWF and *Staphylococcus aureus* V-8 protease–generated vWF fragments with collagen. The binding of purified human vWF to human type III collagen was found to be specific. At saturation, 38 to 50.2 μg of vWF bound per milligram of collagen. Scatchard plots derived from binding isotherms demonstrated the presence of at least two classes of binding sites. Purified vWF was digested with *S aureus* V-8 protease into two complementary fragments (SpIII and SpII). SpII, the C-terminal end of vWF (amino acid residues 1,366 to 2,050), was totally devoid of affinity for collagen. Contrarily, purified SpIII, the N-terminal part of vWF (residues 1 to 1,365), totally displaced vWF binding and specifically bound to collagen. At saturation, 25 to 45 μg of SpIII bound per milligram of collagen. Scatchard plots demonstrated the presence of a single class of binding sites. SpIII was further digested with the same enzyme to generate SpI, a 52-kilodalton fragment from the C-terminal part of SpIII (residues 911 to 1,365). SpI induced a dose-dependent inhibition of both vWF and SpIII binding to collagen. A series of six monoclonal antibodies against SpIII that completely abolished vWF and SpIII interaction with collagen also bound to SpI. In conclusion, SpI extending between amino acid residues 911 and 1,365 of vWF contains a specific site that interacts with human type III collagen.

© 1987 by Grune & Stratton, Inc.

HUMAN VON WILLEBRAND FACTOR (vWF) is a large plasmatic glycoprotein that participates at the site of vessel wall injury in platelet adhesion to subendothelium at high shear rates.[1,2] This function appears to occur by the bridging of platelets to subendothelium components through several sites on vWF, each specific for a distinct receptor. Three systems have been presently identified. Two involve glycoproteins of the platelet membrane,[3] ie, glycoprotein Ib (GPIb)[3-7] and the GPIIb/IIIa complex,[3,8-11] and require the presence of a specific agonist. The third binding site is located in the subendothelium, possibly on the collagen fibers. It has been established that native vWF spontaneously binds to collagen.[12-15]

In plasma, vWF appears as a set of multimers ranging from 0.5 or 1 to more than 15 × 10^6 daltons.[16-18] Each multimer results from the association of disulfide-linked identical subunits composed of 2,050 amino acids with a total molecular weight (mol wt) of 275 kilodaltons (kd).[19-21]

Several studies on the structure-function relationship of vWF have been performed, that are based on limited proteolytic degradation of the protein and the use of monoclonal antibodies (MoAbs) to vWF. These studies have allowed the separation and identification of several domains of vWF involved in its function(s).[22-32] Using *Staphylococcus aureus* V-8 protease (V-8 protease) digestion of vWF, we previously established that the enzyme acted by a primary cut (Glu 1,365 to Glu 1,366) in the vWF subunit.[21,27] This produced two dimeric fragments with a complementary sequence. The C-terminal fragment SpII has a mol wt of 215 kd unreduced and is composed of two identical chains of 110 kd (residues 1,366 to 2,050). This fragment contains the vWF domain interacting with platelet GPIIb/IIIa after thrombin stimulation.[28] The complementary N-terminal fragment SpIII has a mol wt of 320 kd unreduced and is composed of two 170-kd subunits (residues 1 to 1,365). SpIII specifically binds to platelet membrane GPIb in the presence of ristocetin[27-29] and retains the ability to promote platelet adhesion to purified collagen.[30]

Comparison of tryptic[23] and V-8 protease[28] digestion of vWF strongly suggested that a collagen binding domain was located in a central portion of the vWF subunit, between the GPIb and GPIIb/IIIa binding domains (amino acids 728 to 1,365).[31] Pareti et al[32] recently showed, however, that a collagen binding site was located between residues 449 and 728, the same 46-kd tryptic fragment that already contained a GPIb binding domain[25] and a heparin binding site.[26]

To further characterize the collagen binding domains of vWF, we now have investigated the ability of purified SpI, a central fragment of the vWF subunit that does not bind to ristocetin-treated platelets,[27] to interact with collagen. SpI results from a slow, secondary cut by V-8 protease between residues Glu 910 and Gly 911. It corresponds to the C-terminal end of SpIII and is released as a monomeric fragment with a mol wt of 45 kd unreduced and 52 kd reduced. We report here competitive inhibition studies of vWF and SpIII binding to collagen and direct analysis of the interaction between collagen and vWF or vWF fragments. We also used MoAbs to vWF previously characterized as potent inhibitors of vWF binding to collagen, GPIIb/IIIa, or GPIb[15,28] to establish that a functional site of the vWF subunit responsible for binding to collagen is located in the sequence of SpI between amino acid residues Gly 911 and Glu 1,365.

MATERIALS AND METHODS

vWF purification and digestion by V-8 protease. Human vWF was purified from factor VIII/vWF concentrates donated by the Centre National de Transfusion Sanguine, Paris, as described by Thorell and Blombäck.[33] The cryoprecipitate was gently dissolved in

distilled water at 37°C and extensively dialyzed against 25 mmol/L Tris-HCl, pH 7.4, 150 mmol/L NaCl, and 2 mol/L glycine. The precipitate was centrifuged at 10,000 g for 20 minutes at 10°C. vWF was isolated from the supernatant by gel filtration on Sepharose CL-4B (Pharmacia Fine Chemicals AB, Uppsala, Sweden) as already described.[17] Purified vWF was concentrated by precipitation with 40% saturated ammonium sulfate and stored at 80°C. Purified vWF contained 200 to 230 vWF antigen U/mg of protein. It appeared as a set of ten to 11 bands by sodium dodecyl sulfate (SDS) agarose–polyacrylamide gel electrophoresis. The concentration of fibrinogen and fibronectin in vWF preparations was less than 0.1% as estimated by radioimmunoassay.

Proteolysis of vWF by V-8 protease (Miles Laboratories, Inc, Naperville, IL) and the purification of fragments SpI, -II, and -III were carried out as previously described.[27,28] SpI was concentrated by dialysis using UH 100/10 membranes (Schleicher and Schüll, Dassel, FRG).

Characteristics of the MoAbs to vWF. MoAbs to human vWF were produced and characterized as previously described.[34,35] All were $\gamma 1$, κ IgG fractions that were purified from ascites fluids as reported.[35] MoAbs were selected for their ability to specifically inhibit interaction of vWF with either platelets or collagen. MoAbs 311, 322, and H9 block the binding of vWF and SpIII to ristocetin-treated platelets.[15,28,35] MoAbs B200 through B205 inhibit the interaction of vWF with type I collagen.[15] Epitopes 311, 322, H9, and B200 to B205 were previously localized on SpIII.[28] MoAb 9 abolishes the binding of vWF[36] and SpII[28] to thrombin-activated platelets and recognizes an epitope on SpII.[28] In this study an unrelated MoAb to a mammary tumor glycoprotein was used as control IgG.

Radiolabeling. vWF and fragments SpI, SpII, and SpIII were labeled by the method of Fraker and Speck[37] with ^{125}I (Amersham International, Amersham, England) and Iodo-Gen (Pierce Chemical Co, Rockford, IL). Free iodide was separated by gel filtration on a Sephadex G-25 column (Pharmacia) or by extensive dialysis against Tyrode's buffer (130 mmol/L NaCl, 2.6 mmol/L KCl, 12 mmol/L $NaHCO_3$, 5.5 mmol/L glucose, pH 7.2). The specific radioactivity of vWF and SpI, -II, and -III varied from 0.18 to 4.5 μCi/μg of protein. Labeled vWF and fragments were kept at 4°C and used within 24 hours after labeling. Labeled preparations of IgG had a specific radioactivity of 8 to 10 μCi/μg. Nonfibrillar collagen was labeled with Bolton-Hunter reagent.[38] Excess labeled reagent was eliminated by extensive dialysis against 0.1 mol/L acetic acid.

Preparation of collagen fibrils. Lyophilized human nonfibrillar type III collagen was purchased from Sigma Chemical Co, St Louis). This preparation was about 65% pure as determined by hydroxyproline analysis[39] using the content of hydroxyproline in type III collagen previously reported by Miller and Gay.[40] It was about 95% pure when analyzed by SDS–5% polyacrylamide gel electrophoresis,[41] which indicated the absence of contaminating proteins.

Human type III collagen fibrils were prepared from 3-mL aliquots of nonfibrillar collagen dissolved at 1 mg/mL in 0.1 mol/L acetic acid by extensive dialysis for 48 hours at 4°C against 20 mmol/L Na_2HPO_4, pH 7.5.[42] The pellet of collagen fibrils was collected by centrifugation at 20,000 g for one hour at 4°C. It contained 95% to 97% of the starting material as determined in control experiments by radioactivity counting using ^{125}I-collagen. Finally the collagen fibrils were resuspended in 20 mmol/L Na_2HPO_4, pH 7.5, by stirring at 4°C for 16 hours. They were stored for up to 4 weeks at 4°C without apparent loss of activity. Denatured collagen was prepared just before use by heating aliquots of collagen fibrils at 80°C for one hour.

Binding of vWF, SpIII, and SpI to collagen. ^{125}I-labeled vWF or SpIII were centrifuged for three minutes at 10,000 g (Beckman Microfuge M12, Palo Alto, CA) immediately before use. Binding assays were performed in Tyrode's buffer containing 2% bovine serum albumin (BSA) (Tyrode's-BSA buffer) at 22°C in 1.5-mL conical polypropylene tubes. The final mixture (0.2 mL) contained 40 μL of a suspension of collagen fibrils (0.07 to 0.5 mg/mL), 20 μL of a solution of 1% NP40, 100 μL of serial dilutions of ^{125}I-ligand and 40 μL of Tyrode's-BSA buffer. The mixture was incubated for 45 minutes at 22°C. Duplicate aliquots (75 μL) were layered onto 300 μL of 25% sucrose in Tyrode's-BSA buffer in 400-μL conical polyethylene tubes and centrifuged for 15 minutes at 10,000 g. The tips of the tubes containing the pellet were cut with a scalpel, and associated radioactivity was counted in a 1260 multigamma II counter (LKB Instruments SA, Bromma, Sweden). Free ^{125}I-ligand was also measured in the supernatant for each experimental point. Nonspecific binding was estimated as the radioactivity bound to heat-treated collagen. Specific binding was defined as total minus nonspecific binding. Scatchard plots were generated from the specific binding curves. Binding parameters for vWF and SpIII were calculated from experimental values assuming one binding site per subunit with mol wts of 275 and 170 kd, respectively. As established in control experiments using labeled collagen, more than 94% of the collagen fibrils were sedimented in the pellet under our binding assay conditions.

The affinity of iodinated and unlabeled ligand (vWF or SpIII) was compared in the binding assay according to the method described by Pareti et al,[32] using a constant concentration of ligand composed of various proportions of labeled and unlabeled protein. For each ligand, no significant difference in the binding behavior was observed within the range of specific radioactivities used in the present study.

In some experiments, collagen-bound ^{125}I-ligands were washed with Tyrode's buffer and centrifuged for three minutes at 10,000 g. The supernatants were removed and the pellets dissolved for 30 minutes at 37°C in 100 μL of 6 mol/L urea, 1% SDS, and 125 mmol/L Tris-HCl buffer, pH 6.8. The suspensions were centrifuged, and supernatants containing 80% to 90% of the radioactive material were analyzed by SDS–polyacrylamide gel electrophoresis followed by autoradiography.

Binding of ^{125}I-SpI to collagen was performed by using experimental mixtures prepared as described in the binding assay with the only difference being that a constant amount of 1 μg/mL (final concentration) of ^{125}I-ligand was incubated with various amounts (10 to 250 μg/mL final concentration) of collagen fibrils.

Inhibition of binding of ^{125}I-vWF or ^{125}I-SpIII (final concentration, 1 μg/mL) to collagen by unlabeled proteins was performed by using a modified binding assay in which a constant amount of ^{125}I-ligand in Tyrode's-BSA buffer premixed with serial dilutions of unlabeled vWF, SpIII, SpII, or SpI was added to the reaction mixture. Results were expressed by comparison with the specific binding of ^{125}I-ligand estimated in the absence of a competitor.

When the effect of purified MoAbs (IgG) to vWF was analyzed upon ^{125}I-vWF or ^{125}I-SpIII binding, increasing concentrations of IgG were preincubated for 30 minutes at 37°C with a constant amount of ^{125}I-ligand, and the mixture was centrifuged for three minutes at 10,000 g before addition to the other reagents. The supernatant (100 μL) was incubated with collagen (final concentrations, 1 μg/mL of ^{125}I-ligand, 100 μg/mL of collagen).

SDS-gel electrophoresis. SDS-polyacrylamide gel electrophoresis was performed according to Laemmli[43] and Miller and Rhodes.[41] Vertical slab gels were run at 80 V (constant voltage) for 18 hours. SDS-agarose–polyacrylamide slab gel electrophoresis was performed as previously described.[20,28] Markers included low mol wt standards (Pharmacia), purified IgG (mol wt, 160 kd), fibronectin (mol wt, 440 kd), and IgM (mol wt, 900 kd). The gels were stained with Coomassie blue, dried, and autoradiographed at −80°C using Kodak X-Omat S films and X-Omatic cassettes (Eastman Kodak &

Co, Rochester, NY). Alternatively, the gels were blotted onto nitrocellulose paper (Schleicher and Schüll),[44] incubated with ^{125}I-labeled MoAb IgG, and extensively washed with 0.15 mol/L NaCl, and the reactive proteins were visualized by autoradiography.

RESULTS

Binding of vWF to human collagen. Preliminary experiments established that the vWF-collagen interaction was rapid and reached a maximum within 30 minutes and that no significant modification of the equilibrium occurred for 24 hours (data not shown).

When increasing concentrations of purified ^{125}I-vWF were used as the ligand, concentration-dependent and saturable binding to human fibrillar type III collagen (100 μg/mL) was observed. In the experiment described in Fig 1, the total amount of bound vWF increased from 3.5 to 43.6 μg/mg of collagen. Nonspecific binding linearly increased and reached 6.3 μg/mg of collagen at the highest vWF concentration. The binding parameters derived from Scatchard analysis of the specific binding curve indicated that two classes of binding sites were involved in vWF-collagen interactions (Fig 1). At saturation, the maximal binding of vWF was 43 μg/mg of collagen comprising 10 μg/mg with an apparent high affinity K_D of 1.8 μg/mL, and 33 μg/mg with an apparent low affinity K_D of 39 μg/mL. Similar results were obtained in two other experiments using lower concentrations of collagen (15 and 50 μg/mL) and different preparations of labeled vWF (Table 1).

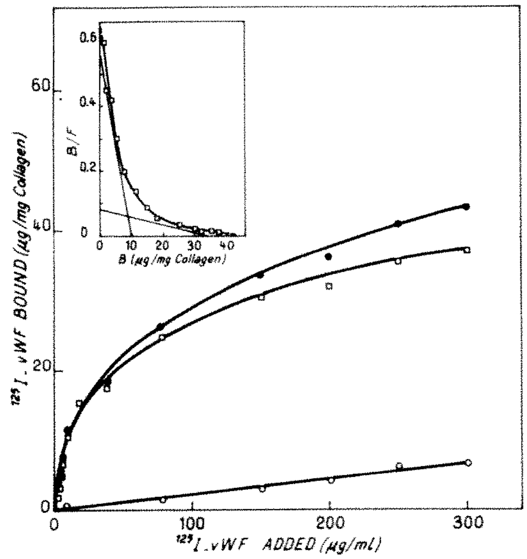

Fig 1. Binding of purified ^{125}I-vWF to collagen. Increasing amounts of ^{125}I-vWF (final concentrations, 1.2 to 300 μg/mL) were incubated at 22°C with a suspension of human type III collagen fibrils. After 45 minutes the collagen-associated radioactivity was separated from free ^{125}I-ligand by centrifugation (15 minutes, 10,000 g) as described in Materials and Methods. In this experiment, ^{125}I-vWF had a specific radioactivity of 0.9 × 10^6 cpm/μg, and the final concentration of collagen was 100 μg/mL. Specific binding (□) was estimated by subtracting nonspecific (O) from total binding (●). Nonspecific binding was measured by using heat-denatured collagen. The inset shows the Scatchard plot derived from the specific binding values.

Table 1. Parameters of Binding of ^{125}I-vWF to Human Fibrillar Type III Collagen

Experiment No.	Collagen (μg/mL)	Bound ^{125}I-vWF (10^{14} sites/mg Collagen) Total	High Affinity	Low Affinity	K_D (10^{-8} mol/L) K_H	K_L
1	15	0.83	0.15	0.68	0.33	10.7
2	50	1.1	0.22	0.88	1.0	21
3	100	0.94	0.22	0.72	0.65	14

Parameters were calculated from Scatchard analysis of the binding isotherms and assuming one binding site per vWF subunit with a mol wt of 275 kd.

Binding of SpIII to human collagen. Binding data obtained using 100 μg/mL of collagen and increasing concentrations of ^{125}I-SpIII (from 1.2 to 300 μg/mL) are shown in Fig 2. Total binding increased from 0.4 to 26.7 μg/mg of collagen. Nonspecific binding linearly increased and reached 4 μg bound/mg of collagen at the highest SpIII concentration. Scatchard analysis of the specific binding curve (Fig 2) indicated that saturation was obtained when 31 μg SpIII bound/mg of collagen and that a single class of sites existed for SpIII with an apparent K_D of 97 μg/mL. Similar results were observed in four separate experiments using different concentrations of collagen and various preparations of labeled SpIII (Table 2).

Inhibition of binding of vWF and SpIII to collagen by specific MoAbs to vWF. In these experiments selected MoAbs to vWF were tested to identify the domain on SpIII and vWF involved in binding to collagen. As illustrated on Fig 3, MoAbs 9 and 322 had no significant inhibitory effect

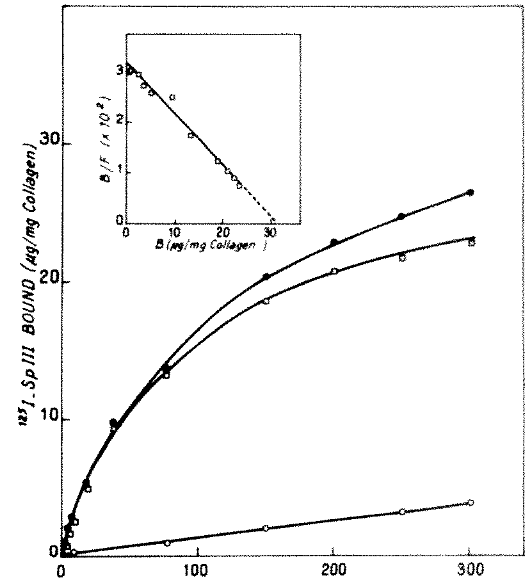

Fig 2. Binding of purified ^{125}I-SpIII to collagen. Increasing amounts of ^{125}I-SpIII (final concentrations, 1.2 to 300 μg/mL) were incubated with human fibrillar type III collagen at 22°C for 45 minutes. In this experiment, ^{125}I-SpIII had a specific radioactivity of 0.6 × 10^6 cpm/μg, and the final concentration of collagen was 100 μg/mL. Specific binding (□) was estimated as described in the legend of Fig 1. The inset shows the Scatchard plot derived from the specific binding values.

Table 2. Parameters of Binding of ^{125}I-SpIII to Human Fibrillar Type III Collagen

Experiment No.	Collagen (μg/mL)	Bound ^{125}I-SpIII (10^{14} Sites/mg Collagen)	K_D (10^{-8} mol/L)
1	15	1.1	35
2	20	1.6	38
3	50	0.9	59
4	100	1.1	57

Parameters were calculated from Scatchard analysis of the specific binding curve and assuming one binding site per SpIII subunit with a mol wt of 170 kd.

upon ^{125}I-vWF or ^{125}I-SpIII binding to collagen. Similar results were obtained when using MoAbs H9 and 311. In contrast, MoAbs B200 to B205, directed towards SpIII and known to inhibit ^{125}I-vWF binding to collagen, also decreased in a dose-dependent manner the binding of ^{125}I-SpIII to collagen. These results were confirmed in four separate experiments in duplicate.

Localization of a collagen binding domain on SpI by using competitive inhibition and direct binding. Purified SpI, -II, and -III fragments produced by selective V-8 protease digestion of vWF were compared with purified vWF for their ability to competitively inhibit binding of ^{125}I-vWF or SpIII to collagen (Fig 4). When ^{125}I-vWF was used as the ligand, complete inhibition of binding was observed with three of the competitors, ie, vWF, SpIII, and SpI. Half-maximum inhibition was reached with 1.5 μg/mL vWF, 105 μg/mL SpIII, and 150 μg/mL SpI, which corresponds to 5.5, 620, and 2,900 nmol/L, respectively. In contrast, even at 500 μg/ml, SpII was unable to compete for the binding of ^{125}I-vWF to collagen. Similar experiments using ^{125}I-SpIII as the ligand confirmed the presence of interactive sites of vWF with collagen on SpIII as well as on SpI (Fig 4). Binding of ^{125}I-SpIII was fully abolished by vWF and by SpIII. It was also almost completely inhibited at the highest concentration (300 μg/ml) of SpI used. Half-maximum inhibition induced by each competitor was reached with 1.0, 40, and 90 μg/mL, respectively, which corresponds to 3.6 nmol/L for vWF, 235 for SpIII, and 1,730 for SpI. SpII at concentrations up to 500 μg/mL did not modify the binding of ^{125}I-SpIII to collagen.

^{125}I-SpI was also tested for its capacity to bind directly to collagen. When using various concentrations (between 10 and 250 μg/mL) of collagen and a constant concentration of ^{125}I-ligand (1 μg/mL), a low but significant and reproducible specific binding of SpI to collagen occurred. The total binding linearly increased from 0.1 ± 0.05% to 2 ± 0.2% (mean ± SD, n = 5) of the added ^{125}I-SpI as compared with a

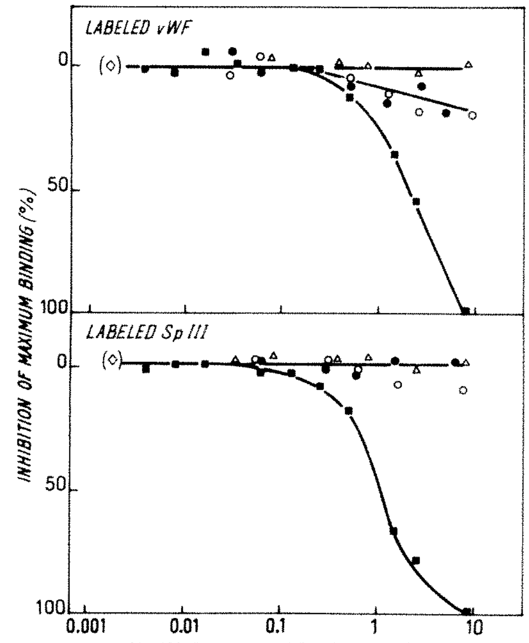

Fig 3. Effect of MoAbs to vWF upon binding of ^{125}I-vWF or SpIII to collagen. Preincubation of ^{125}I-ligand (1 μg/mL, final concentration) with increasing concentrations of MoAb IgG was performed as described in Materials and Methods with 100 μg/mL of human fibrillar type III collagen. In this experiment, the total count in 75-μL aliquots was ~710,000 cpm for ^{125}I-vWF and ~480,000 cpm for ^{125}I-SpIII. In the absence of IgG, total binding was 18% for vWF and 13% for SpIII. Nonspecific binding (3,000 and 1,000 cpm, respectively) did not vary with the concentration of IgG added, and it was subtracted from total binding to estimate specific binding (◊). Results are expressed as percentages of inhibition of specific binding estimated in the absence of IgG. ^{125}I-ligand was incubated with MoAb B203 (■), MoAb 9 (●), MoAb 322 (○), or control MoAb IgG (△).

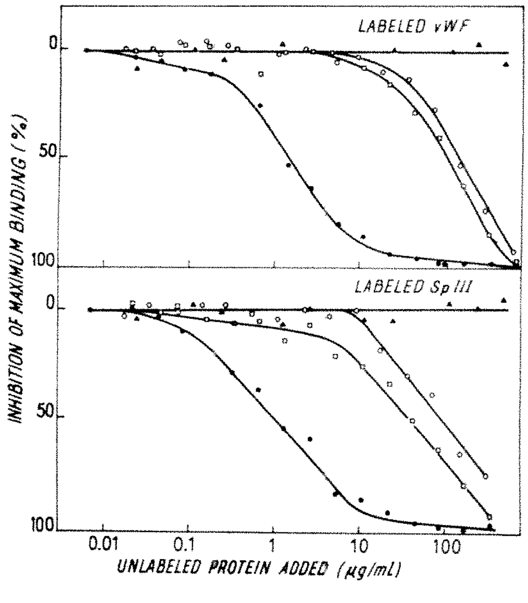

Fig 4. Inhibition of binding of ^{125}I-vWF and ^{125}I-SpIII (1 μg/mL, final concentration) to human collagen by unlabeled vWF or by fragments SpI, SpII, and SpIII. In this experiment, human fibrillar type III collagen (100 μg/mL, final concentration) was added at 22°C to a mixture of either ^{125}I-vWF (9.1×10^6 cpm/μg, top panel) or ^{125}I-SpIII (7×10^6 cpm/μg, bottom panel) with increasing concentrations of unlabeled protein. After 45 minutes, 75-μL aliquots of each sample that contained ~680,000 and ~520,000 cpm, respectively, were centrifuged in duplicate through 25% sucrose as described in Materials and Methods. In the absence of a competitor, the total binding was 23.6% of the applied radioactivity for ^{125}I-vWF and 11% for ^{125}I-SpIII. In both cases nonspecific binding was ~0.7% and did not vary with the concentrations of unlabeled protein added. Results are expressed as percentages of inhibition of specific binding estimated in the absence of competitor. ^{125}I-ligand (vWF or SpIII) was incubated with vWF (●), SpIII (□), SpI (○), or SpII (▲).

nonspecific binding linearly varying from 0.02 ± 0.02% to 0.4 ± 0.08%.

Localization of a collagen binding domain on SpI by using MoAbs to vWF. The presence of a collagen binding domain on purified SpI was confirmed by SDS–polyacrylamide gel electrophoresis followed by immunoblotting with labeled MoAbs to vWF (Fig 5). Purified SpI migrated as a single band with a mol wt of 45 kd (Fig 5, left lane). After blotting, SpI reacted with labeled MoAb B203 (Fig 5, right lane). Similar results were obtained when using the other MoAbs from the same series (B200 to B205) that are known to be specific for the collagen binding domain of vWF and SpIII. In contrast, epitopes 9 and 322 were not detectable on SpI (Fig 5).

DISCUSSION

Our present data, which were obtained using purified fragments SpI, SpII, and SpIII isolated after V-8 protease digestion of vWF, now provide direct evidence that a site specific for collagen is located in the central part of the vWF subunit on fragment SpI between residues 911 and 1,365.

The localization of collagen-interactive sites on SpIII, a dimer of the N-terminal end of vWF (residues 1 to 1,365) already known to bind to platelet GPIb,[27] was clearly established by showing specific saturable binding of this fragment to type III collagen. In addition, the competitive inhibition of ^{125}I-vWF binding by SpIII and of ^{125}I-SpIII binding by vWF strongly suggests that these two species share the same binding domains for collagen. These data are in agreement with previous results showing that SpIII may substitute for vWF in promoting platelet adhesion to collagen at high shear rates.[30] Conversely, SpII, a dimer of the C-terminal end of vWF extending from residues 1,366 to 2,050,[27] demonstrated no ability to interact with collagen by either direct binding assays or competitive inhibition studies. Accordingly, SpII has been shown to have no effect upon platelet adhesion to collagen even though it contains a specific binding domain for platelet GPIIb/IIIa.[28,30]

The localization of collagen-interactive sites on the vWF subunit relies upon the use of MoAbs to vWF B200 to B205, which are specific for SpIII and markedly inhibit vWF binding to type I[15] and type III collagen. Our data show that the occupancy of the corresponding epitopes on SpIII or on vWF produced in both cases a total inhibition of binding of the corresponding proteins to collagen. We showed as a control that MoAbs to SpIII that interfered with binding of SpIII and vWF to platelet GPIb (MoAbs 311, 322, H9) or MoAbs to SpII that blocked binding of SpII or vWF to GPIIb/IIIa (MoAb 9) had no significant effect upon the interaction of vWF or SpIII with collagen. A more precise localization of a specific domain for collagen on the vWF subunit came from results of previous experiments using V-8 protease or trypsin vWF degradation fragments[23,28] as well as specific MoAbs to vWF epitopes involved in binding to platelet GPIb, GPIIb/IIIa, or collagen. We had recently hypothesized that a domain interacting with collagen was located in the central portion of the vWF subunit between the N-terminal GPIb binding site and the C-terminal GPIIb/IIIa binding domain.[31] This hypothesis is now confirmed by our experiments using purified SpI. This monomeric fragment produced by secondary V-8 protease digestion of vWF corresponds to the C-terminal part of SpIII (residues 911 to 1,365) in the central part of the vWF subunit.[27] Our findings establish that SpI totally abolishes the interaction of ^{125}I-vWF and ^{125}I-SpIII with fibrillar human type III collagen. Similar results were observed when using equine type I collagen (not shown). In addition, our data demonstrate that MoAbs B200 to B205, which are known to block vWF binding to collagen and to bind to SpIII, also recognize epitopes located on SpI. We thus conclude that a domain of vWF on SpI accounts for vWF ability to interact with collagen. Our results are in apparent conflict with those recently shown by Pareti et al using tryptic digestion of vWF.[32] These authors showed that a proteolytic fragment of the vWF subunit (residues 449 to 728), which was able to bind to GPIb[25] and to heparin,[26] also contained a domain specific for binding to type I collagen.[32] More recently, using cyanogen bromide fragmentation of reduced and alkylated vWF, Roth et al[45] showed that two sequences, extending from residues 542 to 622 and 948 to 998, respectively, appeared to interfere with the binding of vWF to collagen.[21] Combination of these results thus strongly suggests the presence of at least two binding sites for collagen on each vWF subunit, one in the N-terminal portion and the other in the central part of the vWF subunit.

The relative importance of both domains in the function of native vWF remains to be clarified. Comparison of their affinity for collagen is speculative because vWF fragments isolated after enzymatic degradation may not clearly reflect the function of the corresponding sequences in a native conformation. In the present study, we observed that SpIII, which contains both functional sequences, exhibited a single type of binding site for collagen. These results strongly suggest that the two domains have a similar efficiency in binding. Other lines of evidence suggest that binding of vWF to collagen requires the presence of both sequences on the molecule and that the two sites do not act independently. We thus observed that purified SpI, which apparently contains a single domain, had a low affinity for type III collagen, thereby preventing an accurate estimation of its binding parameters. Nevertheless, this fragment kept the ability to totally inhibit the binding of species containing both active

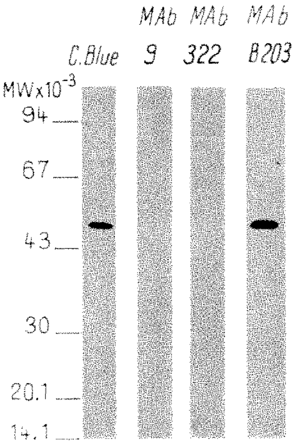

Fig 5. Localization of a vWF domain interacting with collagen by using specific MoAbs to vWF. After SDS–polyacrylamide (7.5%) gel electrophoresis, SpI was stained with Coomassie blue (C.Blue) or transfered onto nitrocellulose paper and displayed by using ^{125}I-IgG from MoAb 9, MoAb 322, or MoAb B203. The position of the mol wt markers is indicated on the left.

sequences like vWF or SpIII. Our hypothesis is further supported by comparing our data of inhibition of binding to collagen by MoAbs to vWF with those recently shown by Pareti et al.[32] These authors found that blocking one epitope between residues 449 and 728 totally inhibited the binding of vWF to collagen, whereas we observed that blocking a single epitope between residues 911 and 1,365 (SpI) also totally abolished binding of vWF, again suggesting that an interaction between both sites is required for binding of vWF to collagen.

The present study also clearly defines the parameters of vWF binding to human type III collagen. We established that its is specific and saturable. Analysis of the binding isotherms demonstrated a biphasic Scatchard plot suggesting the presence of at least two types of interactions. One possibility is the presence of two binding sites with distinct affinity on collagen. vWF subunits may either bind with a high (~1 vWF subunit per 100 to 140 collagen trimers) or a lower affinity (~1 vWF subunit per 20 collagen trimers). These values are consistent with those found by others[32,45] using different types of collagen. However, the two types of binding to collagen were only found under our experimental conditions using human type III collagen. An alternative model should be considered because of the multivalency of the vWF multimers. At low vWF concentrations, ie, an excess of binding receptors on collagen, one may assume that all the vWF subunits in one multimer are bound. Thus, as in the previous model, the mol wt of the ligand molecule would be that of the vWF subunit. The K_D value and number of receptors would be those previously determined for the high-affinity sites. In contrast, at saturating concentrations of vWF, one would expect that a bound multimer would be attached only through one subunit. The other subunits linked by disulfide bridges would be an accurate indication of the mass of vWF bound to collagen but would lead to an overestimation of the vWF subunit directly bound to the receptor. Thus a more accurate estimation of the maximal number of receptors on collagen would be reached by using the average mol wt of the vWF multimers previously established.[20] Using this assumption we found that at saturation only one vWF molecule bound per 130 to 172 collagen trimers. This is in close agreement with the number of vWF molecules bound to collagen trimers experimentally determined for the high-affinity binding sites. Further evidence to support this model is that the homogeneous SpIII molecule that contains the vWF sequences for the putative collagen binding receptors demonstrates only a single type of affinity by Scatchard analysis. Thus, these results suggest that a single type of vWF receptors exists on collagen and that the biphasic Scarchard plot is probably related to the heterogeneity of the multimer size of this large protein.

In conclusion, the present study demonstrates that a collagen interactive site exists in the central part of the vWF subunit, SpI, located from residues 911 to 1,365 in between a previously located N-terminal fragment binding to GPIb, heparin, and collagen[25-29,32,45,46] and a C-terminal fragment previously shown to bind to GPIIb/IIIa.[28] We do not yet know the relative importance of the two collagen binding domains in the function of native vWF. Such information would require a more precise determination of the effect of selected MoAbs upon collagen-vWF interactions.

ACKNOWLEDGMENT

We thank Dr B.R. Bahnak for critical revision of the manuscript. We are grateful to B. Obert, D. Lecoq, and C. Rouault for expert technical assistance and to V. Charles for excellent secretarial help in the preparation of this manuscript.

Expression of c-*abl* in Philadelphia-Positive Acute Myelogenous Leukemia

By Razelle Kurzrock, Mordechai Shtalrid, Moshe Talpaz, William S. Kloetzer, and Jordan U. Gutterman

The identical cytogenetic marker, t(9;22)(q34;q11) (Philadelphia [Ph] translocation), is found in approximately 90%, 20%, and 2% of adult patients with chronic myelogenous leukemia (CML), acute lymphoblastic leukemia (ALL), and acute myelogenous leukemia (AML), respectively. In CML, the molecular events resulting from the Ph translocation include a break within the *bcr* locus on chromosome 22, transfer of the c-*abl* protooncogene from chromosome 9 to 22, and formation of an aberrant 210-kD *bcr-abl* fusion protein (p210$^{bcr\text{-}abl}$). Recently, the absence of *bcr* rearrangement and expression of a distinct aberrant 190-kd *abl* protein (p190$^{c\text{-}abl}$) has been described in Ph-positive ALL, with the suggestion that the two *abl* variants may be pathogenetically associated with myeloid *v* lymphoid leukemogenesis. Here we report that the genomic configuration and translation product of Ph-positive AML can be similar to that of Ph-positive ALL: the break at 22q11 may occur outside the 5.8 kb *bcr* region and result in expression of a 190-kD *abl* protein lacking these *bcr* sequences. Phosphokinase enzymatic activity, a fundamental property of p210$^{bcr\text{-}abl}$, was also associated with AML-derived p190$^{c\text{-}abl}$. Our current observations indicate that p190$^{c\text{-}abl}$ can be found in cells of lymphoid or myeloid lineage and is therefore unlikely to play a specific role in the development of lymphoid leukemias. Formation of p190$^{c\text{-}abl}$ instead of p210$^{bcr\text{-}abl}$ appears to be a characteristic of the acute rather than the chronic Ph-positive leukemic state.

ONE OF THE MOST STRIKING examples of the association between a specific cytogenetic aberration and activation of a cellular protooncogene occurs in chronic myelogenous leukemia (CML). In 1960, Nowell and Hungerford[1] made the seminal discovery of a consistent chromosomal aberration—the Philadelphia (Ph) chromosome—in CML. The Ph chromosome is a shortened chromosome 22 resulting from a reciprocal translocation, t(9;22)(q34;q11).[2] Molecular analysis has revealed that the 22q11 breakpoint occurs within a breakpoint cluster region (*bcr*) spanning about 5.8 kilobase (kb).[3] Importantly, the c-*abl* protooncogene is transferred from its normal residence on chromosome 9 to chromosome 22[4] in juxtaposition to the 5′ *bcr* sequences that remain on the latter chromosome. The resulting fused *bcr-abl* gene expresses a novel 210-kD protein[5]; the normal c-*abl* counterpart is a 145-kD protein.[6] The aberrant 210-kD *bcr-abl* fusion protein (p210$^{bcr\text{-}abl}$) is active as a tyrosine phosphokinase,[5,6] a property of potential fundamental importance to CML because this enzymatic activity has been associated with the ability of several oncogenes and growth factors to exert their effects. Rearrangement of *bcr* and expression of a *bcr-abl* message occur in virtually all patients with CML[7] but not in patients with other hematologic disorders, strongly implicating these molecular events in the pathogenesis of CML.

Approximately 20% of adult patients with acute lymphoblastic leukemia (ALL) also carry the t(9;22)(q34;q11) anomaly.[8] Several investigators have shown molecular heterogeneity of chromosome 22 breakpoints in Ph-positive ALL[9-11]; at least one half of reported patients do not have rearrangement within the 5.8-kb *bcr* locus. The break at 22q11 may occur between the *bcr* and C_λ region of the immunoglobulin light-chain cluster gene.[10] Recently, our laboratory[12] and others[13,14] have demonstrated a novel aberrant 190-kD c-*abl* protein (p190$^{c\text{-}abl}$) in *bcr* rearrangement–negative, Ph-positive ALL; p210$^{bcr\text{-}abl}$ was not found. Presumably, p190$^{c\text{-}abl}$ results from recombination of c-*abl* with a DNA segment upstream of the 5.8 kb *bcr* locus. Based on these results, it appeared that subtle alterations in genomic configuration relative to the *bcr* region may correlate with distinct disease phenotypes. A question that arose is whether the generation of p190$^{c\text{-}abl}$ *v* p210$^{bcr\text{-}abl}$ is associated with the development of a lyphoid as opposed to myeloid phenotype or, alternatively, of an acute rather than a chronic leukemic process. One approach to dissecting these possibilities was to study samples from patients with a rare leukemia subtype—Ph-positive acute myelogenous leukemia (AML). In this paper, we demonstrate absence of *bcr* rearrangement in a Ph-positive AML patient and expression of a 190-kD c-*abl* protein indistinguishable from that found in *bcr* rearrangement–negative, Ph-positive ALL patients. Our results indicate that p190$^{c\text{-}abl}$ is not specific for the lymphoid phenotype but instead may be important in the manifestation of an acute rather than chronic Ph-positive leukemic process.

PATIENT AND METHODS

Case report. In May 1986, patient V1 presented with Ph-positive AML. Her past medical history included a diagnosis of carcinoma of the right breast in 1965. She underwent mastectomy and postoperative chest wall irradiation (5,000 rad). In 1970, a left breast carcinoma was found and subsequently removed by mastectomy. She returned to M.D. Anderson Hospital and Tumor Institute every 4 to 6 months for follow-up evaluation. As part of each visit, a CBC was done. In January 1986, the blood counts were normal: WBC count, $6 \times 10^3/\mu L$ with a normal differential count; hemoglobin, 12.7 g/dL; platelet count, $226 \times 10^3/\mu L$. At the time of her routine return appointment in May 1986, she felt well. There was no evidence of recurrent breast cancer. Surprisingly, laboratory tests revealed a grossly elevated WBC count of $179 \times 10^3/\mu L$ with 94% blasts. Her hemoglobin content was 8.1 g/dL; platelet count, $28 \times 10^3/\mu L$; and leukocyte alkaline phosphatase score, 5% (normal

range, 40% to 225%). A bone marrow aspirate and biopsy specimen revealed a cellularity of 95% with 84% blasts. There was no peripheral blood or bone marrow basophilia. The majority of the bone marrow cells stained positive for myeloperoxidase, consistent with a diagnosis of AML. Reactivity with monoclonal antibody against the differentiation marker My4 was about 50% positive. Cell surface markers for OKT11 (T cell surface marker) and surface immunoglobulin (B cell marker) were negative. These results as well as morphological analysis of the bone marrow by light and electron microscopy indicated a diagnosis of M4 (myelomonocytic) subtype of AML (French-American-British classification). Karyotype analysis (Giemsa-stained chromosomes) revealed a hyperdiploid (51 to 87 chromosomes) Ph-positive clone in 25 of 25 (100%) bone marrow metaphases. The patient was treated with high-dose cytosine arabinoside and achieved complete hematologic remission after one course. However, the aberrant cytogenetic clone persisted in 10% of the cells. The patient remains in hematologic remission at 6+ months. Blood for molecular studies was obtained immediately before initiating chemotherapy and stored at −70°C until analysis. Informed consent, in accordance with institutional guidelines, was obtained for chemotherapeutic procedures and for drawing blood.

Antisera. Rabbit antisera were made against the following peptides: the predicted hydrophilic v-*abl* sequence DEVEKELGKRGTRGG-C (*abl*389-403); the predicted high-term potential domain of c-*abl* (Chou-Fasman predictive model for protien secondary structure, KENLLAGPSENDPN-C (*abl*-3); the region DDESPGLYGFLNV-C (*bcr*3) within *bcr* exon 3; and the NH$_2$-terminal peptide sequence 1 to 17 derived from the Heisterkamp et al[15] *bcr* sequence (*bcr*1). The methodology has been previously reported in detail by Kloetzer et al.[5]

DNA analysis. DNA was prepared by cell lysis, proteinase K digestion, phenol/chloroform extraction, and ethanol precipitation. DNA was analyzed by restriction enzyme digestion, Southern blotting, and hybridization of filters to nick-translated probes. The methodology was identical to that previously used in our laboratory.[12] A 3′, 1.2-kb *bcr* (*Hin*dIII-*Bgl*II) plasmid probe (Oncogene Sciences, Inc, Mineola, NY)[3] and a 5′, 0.45-kb (*Eco*RI/*Pst*I fragment) *bcr* cDNA probe (donated by E. Canaani)[16] were used.

Immune complex kinase assays. Proteins from blood samples were analyzed by the immune complex kinase assay (ICKA) under identical conditions to those previously described by our laboratory.[17] K562 cells (CML erythroid blast crisis cell line) were assayed as controls.

RESULTS

Analysis of leukemia cells for bcr *rearrangement.* To determine whether *bcr* rearrangement was present in patient samples, we performed Southern blotting and hybridization with a 3′, 1.2-kb (*Hin*dIII-*Bgl*II) genomic *bcr* probe. Hybridization of blots of *Bam*HI-, *Bgl*II, *Hin*dIII-, and *Eco*RI-digested DNA did not reveal rearrangement within *bcr* in Ph-positive AML patient V1 (Fig 1, even lanes). In contrast, Fig 1 (odd lanes) illustrates rearranged bands in *Bam*HI-, *Bgl*II, and *Eco*RI-digested, Ph-positive, CML-derived DNA. Because a DNA deletion in the segment encompassing the sequence of the 3′ *bcr* probe could result in a false-negative result for *bcr* rearrangement in AML patient V1,[18] we probed the filters with a 5′ (*Eco*RI/*Pst*I fragment) *bcr* probe.[16] Rearrangement in *bcr* was not observed (data not shown).

Analysis of c-abl *protein expression.* To study c-*abl* protein expression, we perform ICKAs. This assay can detect *abl*-related proteins because they are enzymatically active as phosphokinases. Consistent with our previously published results,[5,12] anti–*abl*389-403 serum and anti-*bcr*3 serum detected p210$^{bcr\text{-}abl}$ in extracts from the K562 CML blast crisis cell line (Fig 2A, lanes 1 and 3). To demonstrate that p210 is *bcr-abl* specific, we preincubated each of the antisera with the peptide against which they were made (Fig 2A, lanes 2 and 4). This procedure results in blocking of antisera-specific bands but not nonspecific background phosphorylation. To date, we have studied fresh samples from 16 Ph-positive CML blast crisis patients (myeloid blast crisis, ten patients; lymphoid, five patients; undifferentiated, one patient); all patients produced p210^{bcr} (Fig 2A, lanes 5 and 6; data not shown).[19] We have recently demonstrated that a Ph-positive ALL patient without *bcr* rearrangement expresses a distinct aberrant p190$^{c\text{-}abl}$ rather than p210$^{bcr\text{-}abl}$.[12] The mRNA encoding p190$^{c\text{-}abl}$ lacks at least some *bcr* sequences and is smaller (7.4 kb) than the 8.5-kb CML-derived *bcr-abl* transcript.[12] As shown in Fig 2A (lanes 7 and 9), *bcr* rearrangement–negative AML patients VI does not produce p210$^{bcr\text{-}abl}$ despite the presence of the Ph translocation; however, a 190-kD *abl*-related protein is detected by two anti-*abl* sera (Fig 2A, lane 7, and Fig 2B, lane 1). Figure 2B (lanes 1 and 3) demonstrates that the *abl*-related product of AML patient V1 comigrates with the p190$^{c\text{-}abl}$ of a Ph-positive *bcr* rearrangement–negative ALL patient.[12] Similar to the situation in ALL,[12] AML-derived p190-^{abl} is not detected by anti-*bcr*3 serum directed against *bcr* exon 3 (Fig 2A, lanes 9 and 10) or by anti-*bcr*l serum directed against the most 5′ portion of the Heisterkamp *bcr* sequences[15] (data not shown).

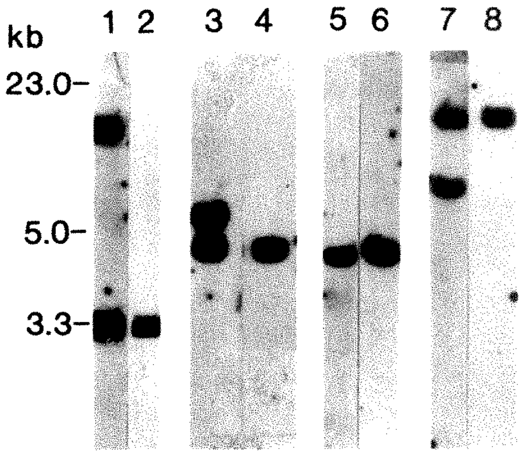

Fig 1. Southern blots of DNA extracted from Ph-positive leukemia patients and hybridized with a 3′, 1.2-kb (*Hin*dIII/*Bgl*II) genomic *bcr* probe (Oncogene Sciences). Restriction enzymes used were *Bam*HI (lanes 1 and 2), *Bgl*II (lanes 3 and 4), *Hin*dIII (lanes 5 and 6), and *Eco*RI (lanes 7 and 8). Odd lanes, Ph-positive CML patient; even lanes, Ph-positive AML patient VI.

A 190,000–molecular weight (mol wt) band is also observed in K562 cells (Fig 2A, lanes 1 and 3). This band may represent a second translational product of *bcr-abl* or a proteolytic fragment of p210$^{bcr\text{-}abl}$. The p190$^{c\text{-}abl}$ of AML patient V1 is distinct from the 190,000–mol wt band of Ph-positive CML cells because anti-*bcr* serum clearly recog-

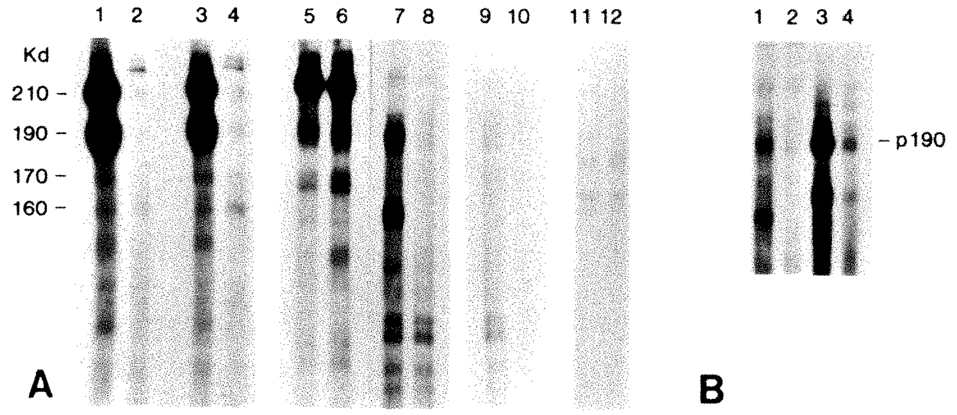

Fig 2. ICKAs. (A) Cells used were as follows: lanes 1 to 4, K562 cells (CML blast crisis cell line); lane 5, CML lymphoid blast crisis patient; lane 6, CML myeloid blast crisis patient; lanes 7 to 10, Ph-positive, *bcr* rearrangement–negative AML patient V1; lanes 11 and 12, Ph-negative AML patient. Antisera used were as follows: lanes 1, 2, 7, 8, 11, and 12, anti-*abl*389-403; lane 5, anti-*abl*3; lanes 3, 4, 6, 9, and 10, anti-*bcr*3. Blocking and antisera with cognate peptide was performed in lanes 2, 4, 8, 10, and 12. (B) Cells used were as follows: lanes 1 and 2, Ph-positive, *bcr* rearrangement–negative AML patient V1; lanes 3 and 4, Ph-positive, *bcr* rearrangement–negative ALL patient. The antiserum used was anti-*abl*3 in all lanes. Blocking of antisera with cognate peptide was performed in lanes 2 and 4.

nizes the latter protein (Fig 2A, lanes 3 and 6). Of course, because of their similar mol wts, we cannot rule out the possibility that CML patients produce $p190^{c\text{-}abl}$ in addition to $p190^{bcr\text{-}abl}$. Similarly, the 170,000–mol wt band in Ph-positive ALL cells (Fig 2B, lane 3) and the 160,000–mol wt protein in Ph-positive AML patient V1 (Fig 2B, lane 1) may also represent proteolytic fragments or additional translational modifications of the *abl* product.

DISCUSSION

The end stage of CML, termed blast crisis, strongly resembles Ph-positive acute leukemia: the leukemic cells lose their capacity for terminal differentiation, and similar clinical characteristics and laboratory parameters are observed.[20] Further, occasional chemotherapy-induced transition of Ph-positive ALL and AML to CML is well documented.[21] Based on these observations, it has been postulated that the disease of some patients presenting with Ph-positive acute leukemia actually represents the blast transformation stage of CML, which escaped diagnosis during its early, often asymptomatic chronic phase. Even so, it seems likely that at least some ALL and AML patients with t(9;22) have a bona fide acute presentation. Because Ph-positive acute leukemia and CML are similar but retain some distinct features, it may be that related but not identical molecular events are involved in their pathogenesis.

Interestingly, some ALL patients carrying a t(9;22), which is cytogenetically indistinguishable from that found in CML, do not have *bcr* rearrangement.[9-11] Our work[12] as well as that of other groups[13,14] has revealed a novel c-*abl* protein—$p190^{c\text{-}abl}$—in Ph-positive, *bcr* rearrangement–negative ALL patients; $p210^{bcr\text{-}abl}$ is not expressed. In the current report, we demonstrate that the Ph tranlocation in AML can also be associated with a 22q11 break outside of the *bcr* locus and production of $p190^{c\text{-}abl}$ without an accompanying $p210^{bcr\text{-}abl}$. Our data suggest that $p190^{c\text{-}abl}$ differs from $p210^{bcr\text{-}abl}$ by virtue of the absence of *bcr* sequences in the N-terminal of the former protein. Similar to the situation in ALL,[12] AML-derived $p190^{c\text{-}abl}$ is enzymatically active as a protein kinase, an observation consistent with a direct role for this aberrant protein in the malignant process. A literature review (Table 1) revealed that about 95% of Ph-positive CML patients (including at least 20 blast crisis patients)[22] but fewer than 50% of Ph-positive acute leukemia patients have *bcr* rearrangement. Further, $p210^{bcr\text{-}abl}$ appears to be expressed in all chronic[19] and acute leukemia patients[12] with *bcr* rearrangement. Although the two molecular subgroups of Ph-positive acute leukemia have similar clinical and morphological features,[10,11] their distinct genomic configurations may have biologic relevance. The presence of *bcr* rearrangement makes Ph-positive acute leukemia virtually indistinguishable from CML blast crisis[20] and suggests a single disease state, with the acute leukemia representing the blast transformation phase of subclinical CML. Conversely, Ph-positive *bcr* rearrangement–negative ALL and AML may reflect true de novo acute leukemia as evidenced by the following: (*a*) *bcr* rearrangement negativity is almost never found in CML and (*b*) $p190^{c\text{-}abl}$ without $p210^{bcr\text{-}abl}$ appears to be associated exclusively with the the acute leukemia phenotype. This concept is supported by our current observations because a preceding undetected CML state can be ruled out in our Ph-positive, *bcr* rearrangement–negative AML patient because of the fortuitous availability of normal blood counts obtained 4 months before diagnosis. Analysis of additional patients will be needed to strengthen the generality of these concepts. However, our data suggest that the presence or absence of proximal *bcr* sequences attached to c-*abl* may modulate this gene's tumorigenic potential for chronic *v* acute leukemogenesis.

Despite the presence of $p190^{c\text{-}abl}$ instead $p210^{bcr\text{-}abl}$, the subgroup of *bcr* rearrangement–negative, Ph-positive acute leukemia patients bears a close clinical resemblance to *bcr* rearrangement–positive, Ph-positive acute leukemia patients,[10,11] and as mentioned earlier, both subgroups resemble CML blast crisis.[20] The molecular events leading to the inevitable malignant evolution of CML from a chronic to an acute leukemia phenotype remain largely unexplored; however, because *bcr* rearrangement is found in the early benign

Table 1. Summary of Studies Analyzing Ph-Positive Leukemia Patients for *bcr* Rearrangement

phase, it seems likely that superimposed secondary genetic events are required. If expression of p190$^{c\text{-}abl}$ without p210$^{bcr\text{-}abl}$ is associated with an acute leukemic state remarkably similar to CML blast crisis, is it possible that the production of p190$^{c\text{-}abl}$ in addition to p210$^{bcr\text{-}abl}$ occurs during the course of CML and plays a role in blast transformation? Further analysis of c-*abl* expression in the nosological spectrum of Ph-positive hematologic malignancies is in progress and should help elucidate the role of molecular variants of this gene on leukemogenesis.

Fibrin Monomer Induces Binding of Endogenous Platelet von Willebrand Factor to the Glycocalicin Portion of Platelet Glycoprotein IB

By Robert I. Parker and Harvey R. Gralnick

This study demonstrates that when platelets are stimulated by thrombin in the presence of low concentrations of purified human fibrinogen (10 to 20 μg/mL, final concentration) binding of released platelet von Willebrand factor (plt-vWF) to the platelet membrane is enhanced. This effect appears to be mediated by fibrin monomer produced by the action of thrombin on the fibrinogen in the incubation suspension. When fibrin polymerization is inhibited, the binding of released plt-vWF to the platelets is markedly increased. This enhanced binding is dependent on platelet glycoprotein Ib (GPIb) as shown by a decreased response with Bernard-Soulier platelets and inhibition by both monoclonal and polyclonal antibodies against glycocalicin. The binding of fibrin to thrombin-activated platelets preincubated with monoclonal antibody against GPIIb/IIIa is increased when the predominant form of fibrin is fibrin monomer. The fibrin binding is also decreased in the presence of antibody against glycocalicin. Our data demonstrate that fibrin monomer facilitates plt-vWF binding to the glycocalicin portion of platelet GPIb on thrombin-stimulated platelets and that binding of fibrin monomer to glycocalicin is necessary for this response to occur.

This is a US government work. There are no restrictions on its use.

PLATELET von Willebrand factor (plt-vWF) is a multimeric glycoprotein localized primarily within platelet α-granules, with a small amount being expressed on the surface of resting platelets.[1-3] Surface expression of plt-vWF markedly increases after thrombin stimulation of platelets by the binding of released plt-vWF to the platelet surface.[3-5] The major platelet receptor involved in the binding of plt-vWF to activated platelets is the glycoprotein IIb/IIIa (GPIIb/IIIa) complex.[6] The thrombin-induced binding of plt-vWF can be inhibited by purified human fibrinogen (≥40 μg/mL) or by a monoclonal antibody directed against the fibrinogen and vWF binding sites on the GPIIb/IIIa complex. In contrast, a monoclonal antibody directed against the ristocetin-induced plasma vWF binding site (GPIb) has no effect on the thrombin-induced plt-vWF binding.[6]

The platelet GPIIb/IIIa complex also binds plasma vWF and fibrinogen when platelets are stimulated by adenosine diphosphate (ADP) or thrombin.[7-10] In addition to binding fibrinogen, thrombin-activated platelets also bind fibrin.[11] Recently, fibrin monomer stabilized on acrylonitrile beads has been shown to bind both plasma vWF and glycocalicin, a water-soluble proteolytic product of GPIb.[12]

In the current study, we demonstrate that the presence of fibrin monomer increases the thrombin-induced binding of endogenous plt-vWF to intact human platelets. The enhanced plt-vWF binding occurs on the glycocalicin portion of GPIb, and it requires the binding of fibrin monomer to the glycocalicin portion of GPIb.

MATERIALS AND METHODS

Platelets were isolated from fresh citrate/EDTA (13 mmol/L sodium citrate, 1mmol/L EDTA)-anticoagulated normal human whole blood by centrifugation of platelet-rich plasma through a discontinuous arabinogalactan (Stractan, Champion International, Tacoma, WA) gradient as previously described.[13] The gradient was sliced at the interface, and the platelets were aspirated and then diluted to a final concentration of 200,000/μL in Tyrode's buffer containing 5 mmol/L $CaCl_2$.

Surface-bound plt-vWF was determined by measuring the binding of a ^{125}I-labeled polyclonal affinity-purified rabbit antihuman vWF antibody to thrombin-stimulated platelets as previously described.[3,6] Briefly, 200-μL aliquots of platelets were incubated with radiolabeled anti-vWF antibody (final concentration, 3.75 μg/mL; 4.8×10^3 cpm/μg) at 37°C for 90 minutes. Various concentrations of purified human firbrinogen (10 to 80 μg/mL, final concentration), bovine serum albumin (BSA), or vWF-free purified human fibronectin (Sigma Chemical Co, St Louis) were included in the incubations. The platelet incubations were carried out in the following fashion: into each polypropylene vial was placed the radiolabeled ligand (anti-vWF or fibrinogen) and/or other proteins (fibrinogen, BSA, fibronectin), and thrombin was then placed along the inside wall of the vial. The amount of thrombin used produced a final concentration of 0.5 U/mL. Platelets were then added to the vial through the thrombin bubble. Fifteen seconds after the addition of the platelets, the thrombin was neutralized by hirudin (grade IV, Sigma; 20 U/mL, final concentration) to prevent fibrin clot formation, and the platelet suspensions were then incubated for 90 minutes at 37°C. In other studies, platelets were activated by calf skin collagen (226 μg/mL, final concentration, Cooper Biologic, Malvern, PA) At the completion of the incubation, bound ligand was separated from free ligand by centrifugation (9000 g for four minutes).

Fibrinogen was purified from lyophylized human-fibrinogen (Kabi grade L, Kabi Diagnostics, Stockholm) by passage over a diethyl aminoethyl (DEAE)-Sephacel column as previously described.[6] Fibrinogen prepared by this method was free of vWF and fibronectin as measured by radioimmunoassay and immunoprecipitation assay, respectively. In some experiments, platelets were preincubated with a saturating amount of a monoclonal antibody directed against the GPIb ristocetin-dependent binding site for plasma vWF (6D1) or against the GPIIb/IIIa binding site of fibrinogen and vWF (10E5). These monoclonal antibodies, provided by Dr B. Coller, State University of New York at Stony Brook, have been shown to have no effect on thrombin-induced platelet shape change or aggregation[8,14] or on thrombin binding to platelets.[15] In other experiments, a polyclonal antiserum monospecific for platelet glycocalicin was included in the incubation suspensions.[16] Because this antiserum inhibits thrombin binding to platelets,[15] it was added

to the platelet suspensions (10%, vol/vol) after the thrombin had been neutralized by hirudin. The incubations were then continued for 90 minutes at 37°C. In some experiments, fibrin polymerization and fibrinogen binding to platelets were prevented by inclusion of the Gly-Pro-Arg-Pro (GPRP) tetrapeptide (Sigma) in the incubation (final concentration, 0.70 mmol/L), and in other experiments, fibrin polymerization was prevented by inclusion of purified bovine fibrinogen fragment D (final concentration, 1 μmol/L).

Platelets from two individuals with Bernard-Soulier syndrome were also studied. Platelets were isolated from citrate/EDTA-anticoagulated fresh whole blood by allowing the RBCs to settle by gravity for three hours at room temperature. Platelet-rich plasma was removed and centrifuged through a Stractan gradient as described earlier.

Fibrin(ogen) binding to activated platelets was measured by incubating 200-μL aliquots of platelets (200,000/μL) with ^{125}I-labeled, purified fibrinogen (7.2 × 10^4 cpm/μg) and α-thrombin or collagen under experimental conditions similar to those used to measure plt-vWF binding. The two exceptions were (*a*) the anti-vWF antibody was omitted and (*b*) the platelets were preincubated with monoclonal antibody 10E5 (20 μg/mL; 15 minutes at 22°C) to prevent binding of fibrinogen to GPIIb/IIIa. Bound fibrinogen was determined by measuring the radioactivity remaining with the platelet pellet. Additional experiments were performed to measure the binding of radiolabeled, purified fibrin(ogen) to platelets incubated with plasma vWF purified from cryoprecipitate (final concentration, 1 μg/mL) and ristocetin (ristocetin sulfate-A, Lenau and Co, Copenhagen; final concentration, 0.6 mg/mL).

The amount of fibrinogen cleaved to fibrin monomer after thrombin treatment was measured as free fibrinopeptide-A (FP-A) (Mallincrodt, St Louis). Purified fibrinogen was incubated with platelets or buffer and exposed to thrombin or collagen in a fashion identical to that described for the plt-vWF binding experiments. The supernatant was removed and frozen at −70°C until assayed for FP-A.

Fibrin monomer polymerization was determined spectrophotometrically by measuring the light absorbance of a suspension of fibrin(ogen) at 350 nm.[17] Purified fibrinogen at various concentrations (10 to 80 μg/mL) in Tyrode's buffer (pH 7.1) was cleaved by the addition of α-thrombin (0.5 U/mL) in either the presence or absence of the inhibitors of fibrin polymerization (GPRP tetrapeptide [0.70 mmol/L], bovine fibrinogen fragment D [1 μmol/L]). Hirudin (20 U/mL) was added 15 seconds after the addition of thrombin to quench the reaction, and from that point fibrin polymerization was followed by measuring the increase in light absorbance at 350-nm wavelength. Maximal fibrin polymerization occurred by five minutes, with no appreciable increase in fibrin polymerization even when the incubations were continued for 90 minutes. The ratio of change in light absorbance at 350 nm for fibrinogen with GPRP or fragment D (at five minutes) to change in light absorbance at 350 nm for fibrinogen without these peptides (at five minutes) corresponds to the fraction of fibrin polymerized. Zero percent polymerization is determined by the increase in 350 nm light absorbance for native fibrinogen without added thrombin, whereas 100% polymerization is determined by the increase in 350-nm light absorbance for fibrinogen cleaved by thrombin in the absence of the inhibitors of fibrin monomer polymerization. The measured amount of FP-A produced relative to the theoretical maximum amount of FP-A production at a given concentration of fibrinogen was used to determine the actual percentage of fibrinogen cleaved to fibrin monomer at that concentration of fibrinogen. Using this value and the percentage of fibrin polymer produced, as observed spectrophotometrically, we estimated the relative amounts of fibrin monomer and fibrin polymer produced under the various experimental conditions.

Thrombin was the kind gift of Dr J. Fenton (NY State, Department of Health, Albany). Bovine fibrinogen fragment D was provided by Dr E. Mihalyi (National Institutes of Health, Bethesda, MD), and the antiglycocalicin antiserum was obtained from Dr N. Solum (University of Oslo). All buffers were made up with distilled, deionized water (<10^{-6} mol/L Ca^{++}), and all chemicals were of reagent grade.

RESULTS

Figure 1 presents the results of plt-vWF binding to thrombin-stimulated platelets in the presence of increasing concen-

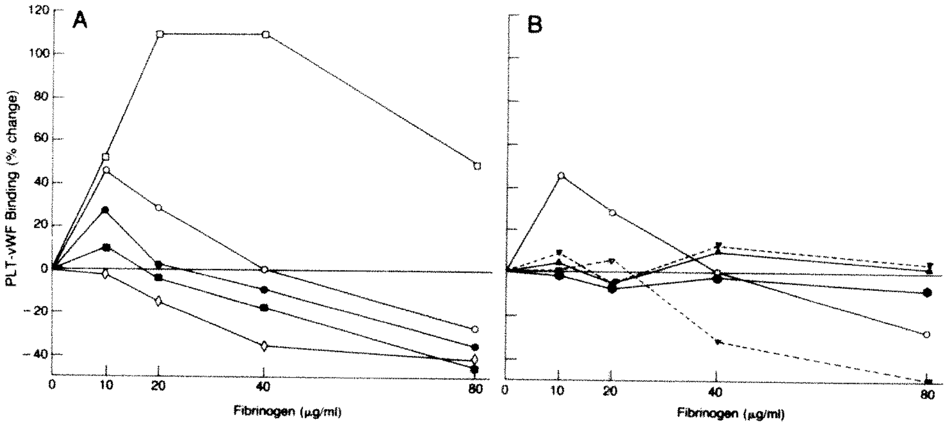

Fig 1. Percent change in plt-vWF surface expression on stimulated platelets in the presence of increasing concentrations of fibrinogen. Plt-vWF binding was determined by the binding of a radiolabeled anti-vWF antibody to platelets (see Materials and Methods). Results represent the means of five to six determinations and are expressed as percent change over control (no added fibrinogen). Aliquots of platelets (200 μL at 200,000/μL) were activated by α-thrombin (0.5 U/mL) or collagen (226 μg/mL). (A) Thrombin-stimulated platelets in the presence of increasing concentrations of fibrinogen and buffer (○), 1 μmol/L fibrinogen fragment D (□), 20 μg/mL 6D1 (●), 10% (vol/vol) α-GC antibody (■), and Bernard-Soulier syndrome platelets (◊). (B) Thrombin-stimulated platelets (○), thrombin-stimulated platelets with 0.70 mmol/L GPRP (▲), and collagen-stimulated platelets (●) in the presence of increasing concentrations of fibrinogen. The broken lines display the results obtained with thrombin-stimulated platelets incubated with increasing concentrations of fibronectin (▽) or BSA (▼). In these experiments, each protein was used in molar concentrations equivalent to those of fibrinogen. Nonspecific binding of the radiolabeled anti-vWF antibody in all experiments was typically less than 4%, and SEM for each point was typically less than 10% and usually less than 5%.

trations of fibrinogen. These data are presented as percent change in plt-vWF binding as compared with control platelets, ie, platelets stimulated by thrombin in the absence of fibrinogen or other plasma proteins. In these experiments fibrin(ogen) at concentrations of 10 and 20 μg/mL enhanced plt-vWF binding to normal thrombin-stimulated platelets, whereas higher concentrations of fibrinogen inhibited plt-vWF binding. A monoclonal antibody known to react with glycocalicin and to block ristocetin-induced binding of plasma-vWF to platelets (6D1) or a polyclonal antiserum monospecific for platelet glycocalicin (α-GC) reduced the fibrin enhancement of plt-vWF binding. The fibrin enhancement of surface bound vWF was not observed in the presence of the GPRP tetrapeptide (which inhibits fibrin polymerization and fibrin binding to platelets) or when Bernard-Soulier platelets were tested. Fibrin-enhanced binding of plt-vWF to the platelet surface was increased, however, when fibrin polymerization was prevented by the inclusion of 1 μmol/L bovine fibrinogen fragment D in the incubation suspensions (Fig 1A).

Fibrinogen had no effect on the surface vWF expression of resting platelets (data not shown) or on platelets stimulated by collagen (Fig 1B). Neither bovine fibrinogen fragment D nor the GPRP tetrapeptide had an effect on plt-vWF binding to thrombin-stimulated platelets in the absence of fibrinogen (data not shown). In other experiments, neither BSA nor purified human fibronectin produced an increase in plt-vWF binding to thrombin-stimulated platelets in the absence of fibrinogen (Fig 1B; broken lines). In the studies that measured plt-vWF binding to platelets, inhibition of plt-vWF binding was noted at high concentrations of fibrinogen (Fig 1A) and fibronectin (Fig 1B). The additional finding that fibrin(ogen) in the presence of the GPRP tetrapeptide has no effect on the binding of released plt-vWF to thrombin-stimulated platelets supports our impression that the fibrin must bind to the platelet surface to have any effect on plt-vWF binding. These results are in agreement with our earlier work that demonstrated that in the absence of fibrin(ogen) released plt-vWF binds to the platelet surface GPIIb/IIIa.[6]

The decreased plt-vWF binding noted in the present experiments is a consequence of competition of plt-vWF with fibronectin or fibrin for this GPIIb/IIIa site. In both our present and prior studies, plt-vWF binding to thrombin-stimulated platelets was never completely inhibited by either fibrinogen or fibronectin. This suggests the possibility of multiple binding sites for plt-vWF on the platelet surface.

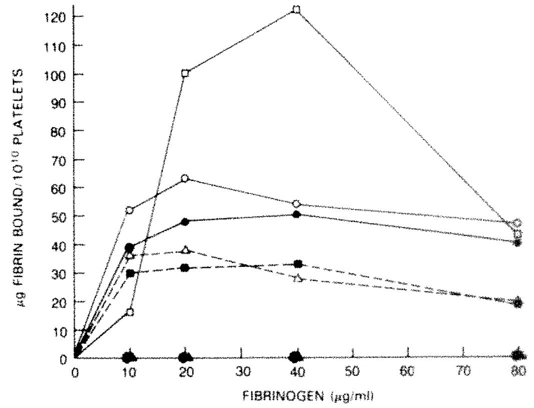

Fig 2. Binding of radiolabeled human fibrin(ogen) to activated platelets. Aliquots of platelets (200 μL at 200,000/μL) were incubated with increasing concentrations of ^{125}I-radiolabeled, DEAE-purified normal human fibrinogen and stimulated by thrombin (○) or collagen (⬤) or by thrombin in the presence of 1 μmol/L fibrinogen fragment D (□), 20 μg/mL 6D1 (●), 0.70 mmol/L GPRP (▲), 1 μg/mL plasma vWF, and 0.6 mg/mL ristocetin (△) or 1 μg/mL plasma vWf and 0.6 mg/mL ristocetin with 1 μmol/L fibrinogen fragment D (■). Platelets were preincubated with 20 μg/mL antibody 10E5 before incubation with fibrinogen. Results represent the means of three determinations; SEM was typically less than 15% for each point and usually less than 10%. Nonspecific binding of the radiolabeled fibrinogen in these experiments was typically 40% to 50%.

Because the enhanced binding of plt-vWF was only seen with thrombin-stimulated platelets and not with collagen-stimulated platelets, we tested whether the fibrinogen must be converted to fibrin to enhance plt-vWF binding. Fibrin(ogen) binding to non-GPIIb/IIIa sites on the platelet was assessed by using platelets preincubated with saturating amounts of anti-GPIIb/IIIa monoclonal antibody (10E5; 20 μg/mL). In these studies, collagen-stimulated platelets bound no radiolabeled fibrinogen, whereas significant amounts of fibrin(ogen) were bound to thrombin-stimulated platelets (Fig 2). The addition of monoclonal antibody 6D1 to platelets already preincubated with monoclonal antibody 10E5 resulted in approximately a 25% reduction in fibrin(ogen) binding to thrombin-stimulated platelets as compared with thrombin-stimulated platelets preincubated with 10E5 alone. The presence of purified plasma vWF and ristocetin (1 μg/mL and 0.6 mg/mL, final concentrations, respectively) resulted in a 30% to 60% reduction of fibrinogen binding with or without added fibrinogen fragment D (1 μmol/L) (Fig 2). In contrast, the addition of fibrinogen fragment D to prevent fibrin polymerization caused a 59% and 126% increase in fibrin binding (compared with thrombin-stimulated platelets with 10E5 alone) at fibrinogen concentrations of 20 and 40 μg/mL, respectively (Fig 2).

The amount of fibrinogen cleaved to fibrin monomer after thrombin treatment was measured as free FP-A. Incubation of fibrinogen with collagen did not result in FP-A production, and the GPRP tetrapeptide did not interfere with the release of FP-A by thrombin (data not shown). The purified fibrinogen did not contain free FP-A. Because fibrin monomer spontaneously polymerizes to form fibrin polymer, we assessed this reaction by measuring light absorbance at 350 nm; this measurement allowed us to calculate the relative amounts of fibrin monomer and polymer present. These data are presented in Table 1. When enhanced binding of plt-vWF and fibrin monomer occurs (as in Figs 1 and 2), Table 1 indicates that fibrin monomer is present in a relative excess over fibrin polymer. These data suggest that fibrin monomer or small fibrin polymers both bind to platelets (at non-GPIIb/IIIa sites) and induce the binding of released plt-vWF to GPIb.

To investigate the relationship between plt-vWF and fibrin monomer binding to the platelet surface, we analyzed the amount of platelet-bound fibrin monomer (Fig 2) *v* the increase in platelet-bound plt-vWF (Fig 1). These data are presented in Fig 3. As indicated, the threshold quantity of
